The free interface separating an exterior, viscous fluid from an intrusive conduit of buoyant, less viscous fluid is known to support strongly nonlinear solitary waves due to a balance between viscosity-induced dispersion and buoyancy-induced nonlinearity. The overtaking, pairwise interaction of weakly nonlinear solitary waves has been classified theoretically for the Korteweg–de Vries equation and experimentally in the context of shallow water waves, but a theoretical and experimental classification of strongly nonlinear solitary wave interactions is lacking. The interactions of large amplitude solitary waves in viscous fluid conduits, a model physical system for the study of one-dimensional, truly dissipationless, dispersive nonlinear waves, are classified. Using a combined numerical and experimental approach, three classes of nonlinear interaction behaviour are identified: purely bimodal, purely unimodal, and a mixed type. The magnitude of the dispersive radiation due to solitary wave interactions is quantified numerically and observed to be beyond the sensitivity of our experiments, suggesting that conduit solitary waves behave as 'physical solitons'. Experimental data are shown to be in excellent agreement with numerical simulations of the reduced model. Experimental movies are available with the online version of the paper.

Key words: pattern formation, solitary waves, Stokesian dynamics

1. Introduction

Exponentially localized solitary waves arise in nature as a balance between the steepening effects of nonlinearity and the spreading effects of dispersion. These fundamental, nonlinear coherent structures exhibit an amplitude-dependent phase speed, often with larger waves propagating faster than slower ones, e.g. Whitham (1974). A distinguishing feature of solitary waves in one dimension is the nature of the resulting interaction when a larger, trailing solitary wave overtakes a smaller, leading wave, a scenario sometimes referred to as strong interaction of solitary waves (Miles 1977). A classical model of weakly nonlinear solitary wave interactions is the Korteweg–de Vries (KdV) equation. Unlike in the case of linear waves, where superposition applies, the nonlinear interaction is characterized by the larger wave decreasing in height and experiencing a forward shift in position, while the

smaller solitary wave increases in amplitude and experiences a negative position shift (Zabusky & Kruskal 1965). The two solitary waves then emerge from the interaction with their initial profiles and speeds restored. The absence of interaction-induced radiation is associated with mathematical solitons and complete integrability of the governing equation, as is the case for KdV. The exact two soliton KdV solution was derived in Hirota (1971) and the soliton overtaking interaction has been classified by amplitude ratio into three distinct regimes according to the qualitative structure during the interaction (Lax 1968). When the ratio of the trailing and leading amplitudes is sufficiently close to unity, a bimodal structure persists through the interaction with the trailing wave passing its mass forward to the leading wave. When the ratio is large, the interaction is unimodal, with the larger wave engulfing the smaller one before emitting it. For intermediate ratios, there is a hybrid state, in which the interaction begins with the larger wave absorbing the smaller one and forming an asymmetric, unimodal mass. During the peak of the interaction, a distinctly bimodal wave appears before the process undoes itself (see figure 2 for images of each interaction type in the context of the model equation considered here). This classification scheme for KdV depends solely on the ratio of the soliton amplitudes due to the existence of scaling and Galilean symmetries. It has been confirmed experimentally in the case of weakly nonlinear, shallow water waves (Weidman & Maxworthy 1978; Craig *et al.* 2006; Li 2012). Due to a capillary instability and small dissipation, solitary water waves are limited to nondimensional amplitudes less than 0.78 (Tanaka 1986; Ablowitz & Haut 2010), thus water waves are a limited system in which to probe large amplitude, conservative solitary wave interactions. Moreover, experiments and numerical simulations of the water wave equations accessed amplitudes only up to 0.4 (Craig *et al.* 2006). Thus, to the authors' knowledge, a systematic, quantitative classification of strongly nonlinear solitary wave interaction behaviours in any physical system is lacking experimentally and theoretically.

In this work, we extend the classification of overtaking interactions of solitary waves to a nonintegrable, strongly nonlinear, dissipationless/dispersive wave equation, the so-called conduit equation (cf. Lowman & Hoefer 2013*a*) and to experiments involving solitary wave interactions with nondimensional amplitudes up to ~ 14. The conduit equation arises in the study of viscous fluid conduits, a medium in which solitary waves have been studied experimentally in isolation (Olson & Christensen 1986; Scott, Stevenson & Whitehead 1986) and post-interaction (Helfrich & Whitehead 1990), but not during the interaction process. The viscous fluid conduit setting is realized by introducing a steady source of buoyant, viscous fluid to a quiescent medium of heavier, more viscous fluid. A stable, fluid-filled pipe is formed. Slow changes in the rate of injection induce interfacial dynamics involving a maximal balance between buoyancy of the intrusive fluid and the resistance to motion by the exterior fluid (see figure 1). The scalar, nonlinear, dispersive conduit equation capturing the interfacial dynamics has been derived from the full set of coupled fluid equations (Lowman & Hoefer 2013*a*). Unlike well-known models of small amplitude, weakly nonlinear, interfacial fluid dynamics such as the KdV (Korteweg & de Vries 1895) and Benjamin–Ono (Benjamin 1967; Ono 1975) equations, the conduit equation is derived under long wave assumptions only, valid for large amplitudes (Lowman & Hoefer 2013*a*), much like the Green–Naghdi (or Serre, Su–Gardner) equations of large amplitude, shallow water waves (Serre 1953; Su & Gardner 1969; Green & Naghdi 1976). Moreover, large amplitude conduit solitary waves are asymptotically stable (Simpson & Weinstein 2008), exhibit good agreement with experiments (Olson & Christensen 1986; Scott *et al.* 1986; Helfrich & Whitehead 1990), and are robust, physical features of viscous fluid conduit interfacial dynamics.
FIGURE 1. (Colour online) Diagram of the fluid conduit experimental system.

Using careful numerical simulations, we find that although the conduit equation does not possess the KdV Galilean invariance, the qualitative Lax classification scheme from KdV theory extends to the strongly nonlinear regime for physically realizable solitary wave amplitudes. The type of interaction depends on the absolute amplitudes of the two waves, rather than solely on their ratio. A scaling invariance of the conduit equation renders a unit solitary wave background but cannot be used to scale individual solitary wave amplitudes. Our numerical computations demonstrate small energy loss (10^{-2} relative change in the solitary wave two-norm) due to interaction, also numerically observed in a closely related equation (Barcilon & Richter 1986). This confirms the non-integrability of the conduit equation, as shown by the Painlevé test (Harris 2006). However, any dispersive radiation following experimental solitary wave interaction was below the resolution of our imaging system, a feature also observed in previous experiments (Helfrich & Whitehead 1990). This suggests that while not mathematical solitons, conduit solitary waves are physical solitons. We support these numerical observations with quantitative interaction classification experiments, which are in excellent agreement and represent the first observations of the mixed and unimodal interaction types in viscous fluid conduits.
FIGURE 2. Example numerical solutions of the conduit equation (2.5) exhibiting the three types of overtaking interactions. The initial and final states, as well as the solution at the time of peak interaction t_i, are plotted on the spatial axis while the left and right insets correspond to the solution just before and just after the peak interaction. The trailing amplitude is varied, while the leading amplitude is fixed, $a_{lead} = 1$. (*a*) Bimodal interaction, $a_{trail} = 3.5$. (*b*) Mixed interaction, $a_{trail} = 5$. (*c*) Unimodal interaction, $a_{trail} = 8$.

The importance of this work extends beyond the remarkable agreement between theoretical and numerical predictions of conduit solitary wave dynamics and our experimental observations. In particular, the overtaking interaction between two solitary waves can be seen as a fundamental property of one-dimensional, dissipationless, dispersive hydrodynamics. As such, these observations further establish the viscous fluid conduit setting as a practically accessible experimental and theoretical platform for future investigations into solitary waves, slowly modulated nonlinear wavetrains, and their interactions, for which quantitative experiments in any physical system are essentially lacking in the literature. Moreover, the fact that we do not observe qualitatively new behaviours in the interactions of solitary waves beyond the weakly nonlinear regime is highly nontrivial due to the lack of integrability and the increased dimensionality of the parameter space. This suggests there could be some robustness or universality to the Lax categories for wave equations which asymptotically reduce to KdV. There is also renewed interest in the nature of two soliton interactions in integrable and nearly integrable systems in connection with the theory of soliton gas (or soliton turbulence) (El & Kamchatnov 2005). Interactions falling into different Lax categories have distinct effects on the statistical

characteristics of soliton turbulence (Pelinovsky *et al.* 2013), and thus viscous fluid conduits provide a promising setting for the experimental study of statistical properties of incoherent soliton gases.

In the following section, we present the theoretical foundations for the classification of conduit solitary waves and describe the experimental set-up. Section 3 presents the details of our findings, and the manuscript is concluded in §4 with a discussion of future directions.

2. Theoretical foundations

In this section, we give an overview of the theoretical foundations needed for classifying viscous fluid conduit solitary wave interactions. We provide intuition regarding the physical effects that give rise to interfacial dynamics, develop relevant numerical tools, and describe the experimental set-up.

2.1. *Derivation of the conduit equation and solitary wave solutions*

A complete mathematical description of the viscous fluid conduit setting requires the consideration of the full system of Navier–Stokes equations for the intrusive and exterior fluids, with boundary conditions along a moving, free interface. To subvert this difficulty, an approximate model governing the interfacial dynamics has been derived from physical principles (Olson & Christensen 1986; Scott *et al.* 1986) and via an asymptotic, multiple scales procedure (Lowman & Hoefer 2013*a*) using the ratio of the viscosities as the small parameter,

$$\epsilon = \mu^{(i)}/\mu^{(e)} \ll 1, \tag{2.1}$$

where $\mu^{(i)}$ indicates the (dynamic) viscosity of the intrusive fluid and $\mu^{(e)}$ that of the exterior fluid. Here we outline the asymptotic derivation and identify the additional key nondimensional quantities and assumptions required to ensure model validity for comparison with experimental parameters.

The steady injection from below of a buoyant, viscous fluid into a basin of a much more viscous fluid evolves to form a vertically uniform, axisymmetric conduit, well-described by the governing equations of Poiseuille-type flow (Whitehead & Luther 1975). In this unperturbed setting, the vertical velocity of the intrusive fluid is driven by a vertical pressure gradient due to buoyancy, and the conduit radius is set by the injection rate, assuming the velocity is $O(\epsilon)$ at the interface. In response to perturbations of the injection rate, radial velocities are excited along the interface, inducing a normal, viscous stress, which balances the pressure difference between the two fluids across the boundary. This dominant balance is satisfied, provided the following assumptions hold: (i) the vertical variation along the conduit wall is small relative to the radial, i.e. the vertical length scale L is large relative to the radius of the unperturbed conduit R_0,

$$L = \left(\frac{A_0}{8\pi\epsilon}\right)^{1/2}, \quad A_0 = \pi R_0^2, \tag{2.2}$$

(ii) the two fluids are miscible with negligible mass diffusion across the interface, and (iii) the Reynolds number of the intrusive fluid, defined to be

$$Re = \frac{\rho^{(i)}UL}{\mu^{(i)}}, \quad U = \frac{gA_0\Delta\rho}{8\pi\mu^{(i)}}, \tag{2.3}$$

for intrusive fluid density $\rho^{(i)}$ and density difference $\Delta\rho = \rho^{(e)} - \rho^{(i)}$, is no larger than $O(1)$. Under these provisions, the vertical pressure gradient within the conduit has two contributions, one from buoyancy and the other from viscous stress. This leads to the (nondimensional) volumetric flux $Q(z, t)$, with characteristic scale Q_0, which can be written in terms of the nondimensional conduit cross-sectional area, $A(z, t)$ in the form

$$Q(z, t) = A^2(z, t) \left\{ 1 - \frac{\partial}{\partial z} \left[\frac{1}{A(z, t)} \frac{\partial A(z, t)}{\partial t} \right] \right\}, \quad Q_0 = A_0 U. \quad (2.4)$$

Lastly, the flux is related to the evolution of the conduit area by appealing to the continuity equation and imposing the kinematic boundary condition along the interface, yielding $\partial_t A(z, t) + \partial_z Q(z, t) = 0$, or the conduit equation

$$\frac{\partial A(z, t)}{\partial t} + \frac{\partial}{\partial z} \left(A^2(z, t) \left\{ 1 - \frac{\partial}{\partial z} \left[\frac{1}{A(z, t)} \frac{\partial A(z, t)}{\partial t} \right] \right\} \right) = 0. \quad (2.5)$$

The conduit equation can be approximated by the KdV equation in the small amplitude, long wavelength regime (Whitehead & Helfrich 1986). A key result for the present study is that (2.5) is valid for long times, $t = o(\epsilon^{-1})$ and large amplitudes $A = o(\epsilon^{-1})$, provided the aforementioned assumptions are satisfied and ϵ is sufficiently small (Lowman & Hoefer 2013a).

Conduit solitary waves, first considered by Scott & Stevenson (1984), are derived by introducing the ansatz $A(z, t) = A(\zeta)$, $\zeta = z - ct$, where c is the wave speed and A decays exponentially to a background constant, here taken to be unity without loss of generality. Inserting this form of the solution into (2.5) and integrating twice yields the ordinary differential equation (ODE) defining the solitary wave profile $A(\zeta)$,

$$\alpha_0 \left(\frac{dA}{d\zeta} \right)^2 = \alpha_1 + \alpha_2 A + \alpha_3 A^2 + \alpha_4 A^2 \ln A, \quad \alpha_0 = \tfrac{1}{2} \left(2A_s^2 \ln A_s - A_s^2 + 1 \right),$$

$$\alpha_1 = A_s^2 \ln A_s - A_s^2 + A_s, \quad \alpha_2 = -2\alpha_0, \quad \alpha_3 = A_s^2 \ln A_s - A_s + 1,$$

$$\alpha_4 = - \left(A_s^2 - 2A_s + 1 \right), \quad (2.6)$$

where A_s is the total height of the solitary wave, i.e. background plus amplitude, and the amplitude–speed relation is given by

$$c(A_s) = \frac{2A_s^2 \ln A_s - A_s^2 + 1}{A_s^2 - 2A_s + 1}. \quad (2.7)$$

Note that the speed is monotone increasing in A_s, so larger solitary waves always move faster.

2.2. *Numerical methods*

To study the overtaking interaction of conduit solitary waves, we initialize A in (2.5) with two well-separated solitary waves. The trailing wave has amplitude a_{trail} ($a = A_s - 1$ is the amplitude above the background) and the lead wave has amplitude a_{lead}. We take $a_{trail} > a_{lead}$ so that $c_{trail} > c_{lead}$. The localized solitary waves are separated initially so that their superposition on a uniform background of unity exhibits small, $O(10^{-7})$, difference above background. The ODE (2.6) is integrated as in Lowman & Hoefer (2013b) with tolerance below $O(10^{-7})$. The dynamical

$\rho^{(i)}$	$\rho^{(e)}$	$\mu^{(i)}$	$\mu^{(e)}$	A_0	U	Re	ϵ
1.23 g ml^{-1}	1.37 g ml^{-1}	0.789 P	83.6 P	0.017 cm^2	0.118 cm s^{-1}	0.049	9.4×10^{-3}

TABLE 1. Key experimental parameters.

solver for (2.5) has been validated in Lowman & Hoefer (2013*b*). The width of the truncated spatial domain is chosen so that, at all times, the solitary waves are 10^{-8} close to the background state at the end points. The grid spacing is chosen so that the individual solitary waves are well-resolved, with values selected from the range $\Delta z \in [0.05, 0.5]$, with larger amplitude solitary waves requiring higher resolution. The time step is $\Delta t = \Delta z / 2c_{trail}$.

2.3. *Experimental set-up*

The experimental apparatus, depicted in figure 1, used to study conduit solitary waves is an acrylic cylinder with square sides 4 cm by 4 cm and a height of 90 cm, filled to a depth of approximately 75 cm with a generic brand light corn syrup. To ensure miscibility, the intrusive fluid was taken to be a 70:30 mixture of corn syrup and water, with food colouring used for imaging. This set-up closely follows previous experiments by Olson & Christensen (1986), Scott *et al.* (1986) and Helfrich & Whitehead (1990). Injection of the intrusive fluid through the base of the apparatus was precisely controlled by use of an automated syringe pump, with the base injection rate 0.1 ml min^{-1} to create a vertically uniform, background conduit. Solitary waves were formed by producing an additional localized pulse in the rate of injection using a second syringe pump, connected to the apparatus via a *y*-junction, hence affording precision control on the size of the solitary waves generated. Viscosities of the two fluids were measured by a rotational viscometer, with 2 % measurement uncertainty. Densities were measured using a scale and graduated cylinder with uncertainty 1 %. Nondimensional, solitary wave amplitudes relative to background were measured by counting pixels across the conduit from still frame images captured with a digital SLR camera. The dimensional radius of the background conduit, held constant throughout the experiments, was measured by comparing images of the background conduit with a grid of known size attached to the back wall of the apparatus. To compute the correction due to the projection of the conduit fluid in the middle of the apparatus onto the back wall, the grid was compared with a copy of the same grid submerged within the filled apparatus before injection commenced. Errors due to imaging techniques and measurement were estimated by measuring the diameter of the background conduit across a range of images yielding a standard deviation of 2 %, of the order of the viscosity measurements. Interaction classification was achieved by high definition video recording of the interaction using a second camera. Still frames of the interactions were then extracted from the video, and downsampled using bicubic interpolation in the vertical coordinate by a factor of $0.1 \approx \epsilon^{1/2}$ in order to enforce an aspect ratio of 1. Recall that the long wavelength scaling in (2.2) sets an aspect ratio of the vertical to radial lengths of order $\epsilon^{-1/2}$. This scaling significantly improves the fidelity with which we can classify the solitary wave interaction types. In cases where it was difficult to determine the classification, edge detection algorithms were also used. Measured and derived fluid properties are provided in table 1.

A major difficulty previously encountered during experiments with this system was creating and maintaining a straight, vertical conduit. We find the following protocol to

be effective. The injection line is prepared so that a small amount of air is left in the line just ahead of the intrusive fluid. The remaining intrusive fluid has no air bubbles. A well-mixed volume of corn syrup is poured down the side of the cylinder to fill, minimizing the entrainment of air. The apparatus is allowed to equilibrate overnight. The experiment is initiated with steady injection at a rate of 0.5 ml min^{-1}. First, controlled air bubbles are produced so that the initial penetration of the intrusive fluid follows behind the air bubbles. This latter protocol is similar to the procedure described in Helfrich & Whitehead (1990). We find the background conduit to be straight to within 0.2° across 60 cm. It merits mention that the conduit equation (2.5) has been shown to be valid for conduits canted by $O(6° \approx \epsilon^{1/2}180°/\pi)$ or less (Lowman & Hoefer 2013a), which was not violated here due to our controlled initiation procedure.

3. Overtaking interactions between strongly nonlinear solitary waves

Using the theoretical, experimental, and numerical techniques developed in the previous section, we now describe the classification of strongly nonlinear solitary wave interactions in the viscous fluid conduit setting. Long time, high resolution numerical simulations in figure 2 exhibit the three interaction categories, which are also found experimentally and displayed in a photo montage in figure 4. It is further shown that the dispersive tail generated by solitary wave interactions is beyond the sensitivity of our experiments.

3.1. *Classification of interactions: KdV*

In the case of the KdV equation, i.e. the weakly nonlinear, long wavelength regime, properties due to integrability have been used to classify the overtaking interaction analytically into three distinct categories, based solely on amplitude ratio a_{trail}/a_{lead} (Lax 1968):

$$1 < \frac{a_{trail}}{a_{lead}} < \frac{3 + \sqrt{5}}{2} \approx 2.62 : \quad \text{bimodal}, \tag{3.1}$$

$$\frac{3 + \sqrt{5}}{2} < \frac{a_{trail}}{a_{lead}} < 3 : \quad \text{mixed}, \tag{3.2}$$

$$\frac{a_{trail}}{a_{lead}} > 3 : \quad \text{unimodal}, \tag{3.3}$$

where a_{trail} and a_{lead} are the trailing and leading soliton amplitudes, respectively for $t \to -\infty$. A bimodal interaction denotes the case where the wave complex maintains a bimodal structure throughout the interaction. This type of exchange interaction corresponds to a transfer of mass from the larger, trailing solitary wave to the smaller, lead solitary wave. In contrast, unimodal interaction involves the complete fusion of the lead wave by the trailing wave, followed by fission into two waves. The intermediate, mixed-type interaction, which has a limited range of amplitude ratios in the weakly nonlinear case, possesses both qualities, a unimodal structure just before and just after interaction but a distinctly bimodal one at $t = t_i$.

3.2. *Classification of interactions: conduit equation*

The numerical classification of strongly interacting solitary waves is achieved by dynamical evolution of the conduit equation (2.5) given initial data consisting of a

large, trailing solitary wave of amplitude a_{trail}, well separated from a smaller, leading solitary wave of amplitude a_{lead}. The geometry of the wave structure near the time of peak interaction, t_i, defined to be

$$t_i = \arg\min_t \left\{ \max_z [A(z, t)] \right\}, \qquad (3.4)$$

is examined. The choice of t_i is due to the nature of the interaction, in which the larger solitary wave decreases in amplitude until $t = t_i$ before asymptotically approaching a_{trail} long after the interaction. This behaviour is characteristic of KdV soliton interactions as well.

We allow the two solitary wave initial profiles to evolve long past the time of interaction ($t_{final} \approx 2t_i$). Once the numerical solution is obtained, the location and height of the two solitary wave maxima are obtained for each time step by interpolating the solution onto a finer grid and examining its derivative to find the local extrema. If only one maximum is found, the structure at that time is considered unimodal. We classify interactions as bimodal if two maxima are present throughout and as unimodal if the interaction possesses only one peak at $t = t_i$. Note that the distinguishing feature of the mixed interaction is the presence of a single maximum just before and after the peak interaction time, but the reemergence of two distinct maxima at $t = t_i$. Example numerical simulations of (2.5) of each type of interaction for a fixed $a_{lead} = 1$ and varying a_{trail} are presented in figure 2.

The bifurcation diagram in figure 3 presents the key results of our classification analysis. For a range of leading and trailing amplitude solitary waves, the critical amplitudes marking phase transition are plotted. This was determined by fixing a_{lead} and monotonically varying a_{trail} in increments of $a_{lead}/20$ until the interaction type had transitioned from one type to another for three consecutively larger values of a_{trail}. The critical value then was taken to be the value of a_{trail} midway between the amplitudes corresponding to the last interaction of one type and the first interaction of the new type. The x marks on the dashed vertical line along $a_{lead} = 1$ mark the location of the simulations presented in figure 2. We find that due to a continuous transition, the precise determination of type I–III requires high resolution simulations.

As pointed out earlier, the behaviour of the conduit equation (2.5) is asymptotically equivalent to KdV in the small amplitude regime, which is captured in the zoomed inset of the phase diagram as the conduit transitions limit on the KdV transitions for sufficiently small $a_{trail} \lessgtr 0.5$. However, in this nonintegrable, strongly nonlinear equation where $2 < a_{trail} < 15$, the type of interaction depends not on the amplitude ratio, but on the values of both amplitudes. This is due to the existence of three distinct conduit amplitudes, the background and those of the trailing and leading solitary waves. Only one amplitude can be scaled to unity using symmetry of the equation, leaving two other free parameters (cf. Lowman & Hoefer 2013b).

The complete, mathematical classification of KdV soliton interactions was enabled by an explicit representation of the solution. Here, we do not have this luxury. Like in the integrable setting, though, the structure of the interaction for every amplitude tested in our simulations (which covers most of the physically relevant range) always falls into one of the three types. Moreover, the mixed geometry is expected for a much wider range of amplitudes than in (3.1) as the two initial waves grow larger.
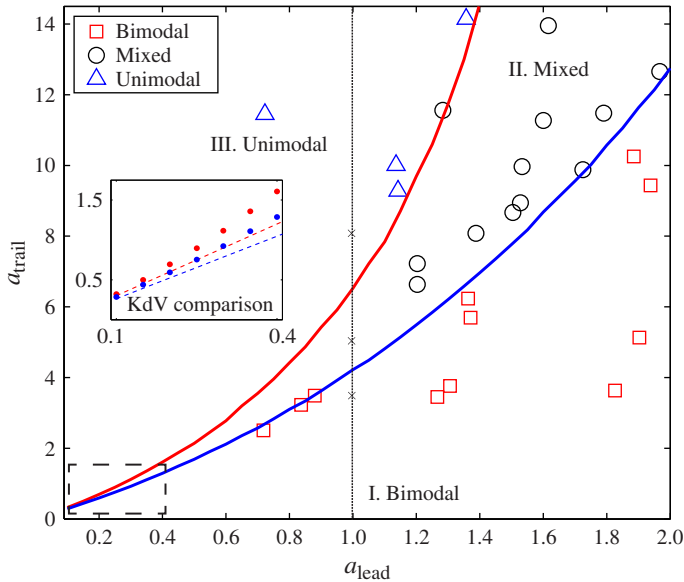

FIGURE 3. (Colour online) Phase diagram of the numerical and experimental classification of the overtaking interaction between two conduit solitary waves as a function of the leading and trailing wave amplitudes. The blue (top) curve indicates the transition from bimodal interaction to the intermediate/mixed type. The red (bottom) curve marks the transition from the mixed type to unimodal. The inset represents the boxed portion in the weakly nonlinear regime showing convergence to the KdV predictions (dashed lines). Crosses along $a_{lead} = 1$ correspond to simulations in figure 2. The geometric shapes correspond to experimental classification.

3.3. *Radiation emitted due to interaction*

It is also of physical interest to consider the magnitude of the dispersive tail resulting from interactions of conduit solitary waves, which are not exact solitons. Overtaking interactions of solitary waves in nonintegrable equations have been shown via numerical simulations to produce a small tail of linear dispersive waves following their interaction, e.g. (Bona, Pritchard & Scott 1980; Mirie & Su 1982; Barcilon & Richter 1986), a feature which, if sufficiently large, could be examined experimentally. To address this issue, we have run simulations of solitary wave interactions for a fixed $a_{lead} = 1$ and a_{trail} varying between 2 and 8, so that it spans all three interaction types and also corresponds to the experiments in the following section. The radiation was quantified in two ways using long time numerical evolution, $t_{final} \approx 3t_i$. The first is the change in the amplitudes of the solitary waves post-interaction and the second is the change in the profiles. Here we find the maximum change in amplitudes for both waves is consistently $O(10^{-3})$. The change in the individual solitary wave profiles is determined by centring a window about each individual wave, for both the initial and final times, and then determining the residual between the two profiles, here defined by the relative two-norm difference, i.e. the two-norm of the residual divided by the initial two-norm. This metric reveals that the change in profiles from before to long after the interaction is not larger than $O(10^{-2})$ across the simulations examined. These findings are consistent not only with numerical simulations of a closely related equation (Barcilon & Richter 1986), but also with experimental findings from conduit solitary wave interactions (Helfrich & Whitehead 1990). Moreover, the amplitude
FIGURE 4. (Colour online) Data from interaction experiments. (*a*) Unscaled data showing the solitary wave profiles from a typical interaction. (*b*) Examples of the three interaction types for scaled data used in classifications. From top to bottom, (a_{lead}, a_{trail}) are (1.27, 3.45), (1.53, 9.97), and (1.14, 10.01), respectively. See the online version of the paper for movies of these experiments.

differences and residuals are beyond the sensitivity of our experimental capabilities, which suggests that these conduit solitary waves are approximately solitons, at least in a physical sense. Hence we term them 'physical solitons'.

3.4. *Experimental observation of the three types of interaction*

In figure 3, we plot the results of twenty-seven solitary wave interaction classification experiments. The three distinct types predicted by numerical simulations of the conduit equation (2.5) are readily observable in the full physical system, and their dependence on a_{lead} and a_{trail} is in excellent agreement with the phase diagram. Example images of an unscaled interaction experiment and then scaled data used for classification are given in figure 4. While it is sometimes difficult to distinguish between the regimes in the unscaled data, scaling the data recovers the aspect ratio of the nondimensional coordinate system from the numerical simulations and allows for proper determination. Typical examples of the three interaction types are shown. Movies in both unscaled and scaled formats are available with the online version of the paper at http://dx.doi.org/10.1017/jfm.2014.273.

Regarding the agreement with numerical simulations, up to the 2% error in measuring conduit diameters, the data all lie in the appropriate regions of the phase diagram. While this agreement is compelling on its own, it is also possible to compare

with the approximate model breakdown criteria identified in Lowman & Hoefer (2013*a*). The use of miscible fluids meets the negligible surface tension criterion, and the contributions due to the outer wall are small because the nondimensional radius of the outer wall satisfies $R_{wall} \approx 76 \gg \epsilon^{-1/2} = 10.3$. The Reynolds number criterion $Re = 0.049 \ll \epsilon^{-1} = 106$ for neglecting inertial effects is also satisfied. Lastly, the breakdown of the multiple scales assumption occurs when the condition, $A \ll 1/8\epsilon \approx 13.3$, is violated for large amplitude solitary waves (Lowman & Hoefer 2013*a*). We note that two of the trials lie beyond this point, though they still fall in the appropriate classification region. There exists an independent condition for model validity based on the introduction of inertial effects for sufficiently large amplitude solitary waves, measured by an effective solitary wave Reynolds number (Helfrich & Whitehead 1990), but we find the multiple scales condition to be more restrictive in our case. Our results suggest remarkably robust concurrence between the reduced, approximate interfacial equation and the full two-fluid system.

4. Summary and conclusions

The qualitative characterization of large amplitude, pairwise solitary wave interactions in viscous fluid conduits has been shown to permit geometric classification according to the three Lax categories for KdV. Unlike the weakly nonlinear regime, however, the expected interaction type depends on the wave amplitudes, rather than only their ratio, and the mixed unimodal/bimodal interaction type is a more robust, readily observable feature than for surface water waves.

The long time, large amplitude validity of the conduit equation (2.5) and its analytical tractability make this two viscous fluid setting an ideal one for the study of nonlinear dispersive waves. That nonlinear dispersive waves occur at all in a fully viscous setting is a nontrivial observation, but that the reduced equation captures the geometry of interacting solitary waves suggests the interfacial dynamics of viscous fluid conduits are, as predicted, approximately one-dimensional and dissipationless at the time scales under consideration. Moreover, the absence of dispersive radiation in the experiments implies that, while the conduit equation is not completely integrable, its solitary waves practically interact elastically. These results encourage future experimental studies on nonlinear coherent structures, such as rarefaction waves, slowly modulated wavetrains (dispersive shock waves) and their interactions.
