**In a constantly changing world, animals must account for environmental volatility when making decisions. To appropriately discount older, irrelevant information, they need to learn the rate at which the environment changes. We develop an ideal observer model capable of inferring the present state of the environment along with its rate of change. Key to this computation is an update of the posterior probability of all possible change point counts. This computation can be challenging, as the number of possibilities grows rapidly with time. However, we show how the computations can be simplified in the continuum limit by a moment closure approximation. The resulting low-dimensional system can be used to infer the environmental state and change rate with accuracy comparable to the ideal observer. The approximate computations can be performed by a neural network model via a rate-correlation-based plasticity rule. We thus show how optimal observers accumulate evidence in changing**

## **environments and map this computation to reduced models that perform inference using plausible neural mechanisms.**

### **1 Introduction**

---

Animals continuously make decisions in order to find food, identify mates, and avoid predators. However, the world is seldom static. Information that was critical yesterday may be of little value now. Thus, when accumulating evidence to decide on a course of action, animals weight new evidence more strongly than old (Pearson, Heilbronner, Barack, Hayden, & Platt, 2011). The rate at which the world changes determines the rate at which an individual should discount previous information (Deneve, 2008; Veliz-Cuba, Kilpatrick, & Josić, 2016). For instance, when actively tracking prey, a predator may use visual information obtained only within the last second (Olberg, Worthington, & Venator, 2000; Portugues & Engert, 2009), while social insect colonies integrate evidence that can be hours to days old when deciding on a new home site (Franks, Pratt, Mallon, Britton, & Sumpter, 2002). These environmental state variables (e.g., prey location, best home site) are constantly changing, and the timescale on which the environment changes is unlikely to be known in advance. Thus, to make accurate decisions, animals must learn how rapidly their environment changes (Wilson, Nassar, & Gold, 2010).

Evidence accumulators are often used to model decision processes in static and fluctuating environments (Smith & Ratcliff, 2004; Bogacz, Brown, Moehlis, Holmes, & Cohen, 2006). These models show how noisy observations can be accumulated to provide a probability that one among multiple alternatives is correct (Gold & Shadlen, 2007; Beck et al., 2008). They explain a variety of behavioral data (Ratcliff & McKoon, 2008; Brunton, Botvinick, & Brody, 2013), and electrophysiological recordings suggest that neural activity can reflect the accumulation of evidence (Huk & Shadlen, 2005; Kira, Yang, & Shadlen, 2015). Since normative evidence accumulation models determine the belief of an ideal observer, they also show the best way to integrate noisy sensory measurements and can tell us if and how animals fail to use such information optimally (Bogacz et al., 2006; Beck et al., 2008).

Early decision-making models focused on decisions between two choices in a static environment (Wald & Wolfowitz, 1948; Gold & Shadlen, 2007). Recent studies have extended this work to more ecologically relevant situations, including multiple alternatives (Churchland, Kiani, & Shadlen, 2008; Krajbich & Rangel, 2011), multidimensional environments (Niv, Daniel, Geana, Gershman, Leong, & Radulescu, 2015), and cases where the correct choice (McGuire, Nassar, Gold, & Kable, 2014; Glaze, Kable, & Gold, 2015) or context (Shvartsman, Srivastava, & Cohen, 2015) changes in time. In these cases, normative models are more difficult to derive and analyze (Wilson & Niv, 2011), and their dynamics are more complex. However, methods

of sequential and stochastic analysis are still useful in understanding their properties (Wilson et al., 2010; Veliz-Cuba et al., 2016).

We examine the case of a changing environment where an optimal observer discounts prior evidence at a rate determined by environmental volatility. In this work, a model performs optimally if it maximizes the likelihood of predicting the correct environmental state, given the noise in observations (Bogacz et al., 2006). Experiments suggest that humans learn the rate of environmental fluctuations to make choices nearly optimally (Glaze et al., 2015). During dynamic foraging experiments where the choice with the highest reward changes in time, monkeys also appear to use an evidence discounting strategy suited to the environmental change rate (Sugrue, Corrado, & Newsome, 2004).

However, most previous models have assumed that the rate of change of the environment is known ahead of time to the observer (Glaze et al., 2015; Veliz-Cuba et al., 2016). Wilson et al. (2010) developed a model of an observer that infers the rate of environmental change from observations. To do so, the observer computes a joint posterior probability of the state of the environment, the time since the last change in the environment, and a count of the number of times the environment has changed (the change point count). With more measurements, such observers improve their estimates of the change rate and are therefore better able to predict the environmental state. Inference of the change rate is most important when an observer makes fairly noisy measurements and cannot determine the current state from a single observation.

We extend previous accumulator models of decision making to the case of multiple, discrete choices with asymmetric, unknown transition rates between them. We assume that the observer is primarily interested in the current state of the environment, often referred to as the correct choice in decision-making models (Bogacz et al., 2006). Therefore, we show how an ideal observer can use sensory evidence to infer the rates at which the environment transitions between states and simultaneously use these inferred rates to discount old evidence and determine the present environmental state.

Related models have been studied (Wilson et al., 2010; Adams & MacKay, 2007). However, they relied on the assumption that after a change, the new state does not depend on the previous state. This excludes the possibility of a finite number of states. For example, in the case of two choices, knowledge of the present state determines with complete certainty the state after a change, and the two are thus not independent. For cases with a finite number of choices, our algorithm is simpler than previous ones. The observer only needs to compute a joint probability of the environmental state and the change point count.

The storage needed to implement our algorithms grows rapidly with the number of possible environmental states. However, we show that moment closure methods can be used to decrease the needed storage considerably,

albeit at the expense of accuracy and the representation of higher-order statistics. Nonetheless, when measurement noise is not too large, these approximations can be used to estimate the most likely transition rate and the current state of the environment. This motivates a physiologically plausible neural implementation for the present computation. We show that a Hebbian learning rule that shapes interactions between multiple neural populations representing the different choices allows a network to integrate inputs nearly optimally. Our work therefore links statistical principles for optimal inference with stochastic neural rate models that can adapt to the environmental volatility to make near-optimal decisions in a changing environment.

## 2 Optimal Evidence Accumulation for Known Transition Rates ---

We start by revisiting the problem of inferring the current state of the environment from a sequence of noisy observations. We assume that the number of states is finite and the state of the environment changes at times unknown to the observer. We first review the case when the rate of these changes is known to the observer. In later sections, we assume that these rates must also be learned. Following Veliz-Cuba et al. (2016), we derived a recursive equation for the likelihoods of the different states and an approximating stochastic differential equation (SDE). Similar derivations were presented for decisions between two choices by Deneve (2008) and Glaze et al. (2015).

An ideal observer decides between  $N$  choices, based on successive observations at times  $t_n$  ( $n = 1, 2, \dots$ ). We denote each possible choice by  $H^i$ , ( $i = 1, \dots, N$ ), with  $H_n$  being the correct choice at time  $t_n$ . The transition rates  $\epsilon^{ij}$ ,  $i \neq j$ , correspond to the known probabilities that the state changes between two observations:  $\epsilon^{ij} = P(H_n = H^i | H_{n-1} = H^j)$ . The observer makes measurements,  $\xi_n$ , at times  $t_n$  with known conditional probability densities  $f^i(\xi) = P(\xi_n = \xi | H_n = H^i)$ . Here, and elsewhere, we assume that the observations are conditionally independent. We also abuse notation slightly by using  $P(\cdot)$  to denote a probability, or the value of a probability density function, depending on the argument. We use explicit notation for the probability density function when there is a potential for confusion.

We denote by  $\xi_{j:n}$  the vector of observations  $(\xi_j, \dots, \xi_n)$  and by  $P_n(\cdot)$  the conditional probability  $P(\cdot | \xi_{1:n})$ . To make a decision, the observer can compute the index that maximizes the posterior probability,  $\hat{i} = \operatorname{argmax}_i P_n(H_n = H^i)$ . Therefore,  $H^{\hat{i}}$  is the most probable state, given the observations  $\xi_{1:n}$ .

A recursive equation for the update of each of the probabilities  $P_n(H_n = H^i)$  after the  $n$ th observation has the form (Veliz-Cuba et al., 2016)

$$P_n(H_n = H^i) \propto f^i(\xi_n) \sum_{j=1}^N \epsilon^{ij} P_{n-1}(H_{n-1} = H^j) \quad (i = 1, \dots, N). \quad (2.1)$$

Thus, the transition rates,  $\epsilon^{ij}$ , provide the weights of the previous probabilities in the update equation. Unless transition rates are large or observations very noisy, the probability  $P_n(H_n = H^i)$  grows and can be used to identify the present environmental state. However, with positive transition rates, the posterior probabilities tend to saturate at a value below unity. Strong observational evidence that contradicts an observer’s current belief can cause the observer to change belief subsequently. Such contradictory evidence typically arrives after a change in the environment.

Following Veliz-Cuba et al. (2016), we take logarithms,  $x_n^i := \ln P_n(H_n = H^i)$  and denote by  $\Delta x_n^i := x_n^i - x_{n-1}^i$  the change in log probability due to an observation at time  $t_n$ . Finally, we assume the time between observations  $\Delta t := t_n - t_{n-1}$  is small, and  $\epsilon_{\Delta t}^{ij} = \Delta t \epsilon^{ij} + o(\Delta t)$  for  $i \neq j$ , so that dropping higher-order terms yields

$$\Delta x_n^i = \ln f_{\Delta t}^i(\xi_n) + \ln \left( 1 - \sum_{j \neq i} \Delta t \epsilon^{ji} + \sum_{j \neq i} \Delta t \epsilon^{ij} e^{x_{n-1}^j - x_{n-1}^i} \right), \quad i = 1, \dots, N,$$

where the likelihood function  $f_{\Delta t}^i(\xi)$  may vary with  $\Delta t$ . Next, we use the approximation  $\ln(1 + z) \approx z$  for  $|z| \ll 1$  and replace the index  $n$  by time,  $t$ , to write

$$\Delta x_t^i \approx \Delta t g_{t, \Delta t}^i + \sqrt{\Delta t} W_{\Delta t}^i + \Delta t \sum_{j \neq i} (\epsilon^{ij} e^{x_t^j - x_t^i} - \epsilon^{ji}), \quad i = 1, \dots, N,$$

where the drift  $g_t^i = \frac{1}{\Delta t} E_{\xi} [\ln f_{\Delta t}^i(\xi) | H_t]$  is the expectation of  $\ln f_{\Delta t}^i(\xi)$  over  $\xi$ , conditioned on the true state of the environment at time  $t$ ,  $H_t \in \{H^1, \dots, H^N\}$ , and  $W_{\Delta t} = (W_{\Delta t}^1, \dots, W_{\Delta t}^N)$  follows a multivariate gaussian distribution with mean zero and covariance matrix  $\Sigma_{\Delta t}$  given by

$$\Sigma_{\Delta t}^{ij} = \frac{1}{\Delta t} \text{Cov}_{\xi} [\ln f_{\Delta t}^i(\xi), \ln f_{\Delta t}^j(\xi) | H_t].$$

Finally, taking the limit  $\Delta t \rightarrow 0$ , we can approximate the discrete process, equation 2.1, with the system of SDEs:

$$dx_t^i = g_t^i dt + dW_t^i + \sum_{j \neq i} (\epsilon^{ij} e^{x_t^j - x_t^i} - \epsilon^{ji}) dt, \quad i = 1, \dots, N, \quad (2.2)$$

where we assume the following limits hold:

$$g_t^i := \lim_{\Delta t \rightarrow 0} g_{t, \Delta t}^i \quad \text{and} \quad \Sigma_t^{ij} := \lim_{\Delta t \rightarrow 0} \Sigma_{t, \Delta t}^{ij}.$$

The nonlinear term in equation 2.2 implies that in the absence of noise, the system has a stable fixed point and older evidence is discounted. Such continuum models of evidence accumulation are useful because they are amenable to the methods of stochastic analysis (Bogacz et al., 2006). Linearization of the SDE provides insights into the system's local dynamics (Glaze et al., 2015; Veliz-Cuba et al., 2016) and can be used to implement the inference process in model neural networks (Bogacz et al., 2006; Veliz-Cuba et al., 2016).

We next extend this approach to the case when the observer infers the transition rates,  $\epsilon^{ij}$ , from measurements.

### 3 Environments with Symmetric Transition Rates

We first derive the ideal observer model when the unknown transition rates are symmetric,  $\epsilon^{ij} \equiv \text{constant}$  when  $j \neq i$ , and  $\epsilon^{ii} := 1 - (N - 1)\epsilon^{ij}$ . This simplifies the derivation, since the observer only needs to estimate a single change-point count. The asymmetric case discussed in section 4 follows the same idea, but the derivation is more involved since the observer must estimate multiple counts.

Our problem differs from previous studies in two key ways (Adams & MacKay, 2007; Wilson et al., 2010): First, we assume the observer tries to identify the most likely state of the environment at time  $t_n$ . To do so, the observer computes the joint conditional probability,  $P_n(H_n, a_n)$ , of the current state,  $H_n$ , and the number of environmental changes,  $a_n$ , since beginning the observations. Previous studies focused on obtaining the predictive distribution,  $P_n(H_{n+1})$ . The two distributions are closely related, as  $P_n(H_{n+1}) = \sum_{H_n} P_n(H_{n+1}|H_n)P_n(H_n)$ .

Second, and more important, Adams and Mackay (2007) and Wilson et al. (2010) implicitly assumed that only observations since the last change point provide information about the current environmental state. That is, if the time since the last change point—the current run length,  $r_n$ —is known to the observer, then all observations before that time can be discarded:

$$P(H_n|\xi_{1:n}, r_n) = P(H_n|\xi_{n-r_n:n}).$$

This follows from the assumption that the state after a change is conditionally independent of the state that preceded it. We assume that the number of environmental states is finite. Hence, this independence assumption does not hold. Intuitively, if observations prior to a change point indicate the true state is  $H^j$ , then states  $H^i$ ,  $i \neq j$  are more likely after the change point.

Adams and Mackay (2007) and Wilson et al. (2010) derive a probability update equation for the run length and the number of change points and use this equation to obtain the predictive distribution of future observations. We show that it is not necessary to compute run-length probabilities when

Figure 1: Online inference of the change rate in a dynamic environment. (A) The environment alternates between states  $H^+$  and  $H^-$  with transition probabilities  $\epsilon^+$ ,  $\epsilon^-$ . We analyze the symmetric case ( $\epsilon := \epsilon^\pm$ ) in section 3.1 and the asymmetric case ( $\epsilon^+ \neq \epsilon^-$ ) in section 4. The state of the environment determines  $f^\pm(\xi) = P(\xi | H^\pm)$ , which we represent as gaussian densities. (B) A sample path of the environment (color bar) together with the first 10 values of the actual change-point count,  $a_n$ , and non-change-point count,  $b_n$ . (C) Evolution of the conditional probabilities,  $P(\epsilon | a_n)$  (given by beta distributions), corresponding to the change-point count from panel B, until  $t_n = t_{100}$ . The dashed red line indicates the value of  $\epsilon$  in the simulation. The densities are scaled so that each equals 1 at the mode.

the number of environmental states is finite. Instead we derive a recursive equation for the joint probability of the current state,  $H_n$ , and number of change points,  $a_n$ . As a result, the total number of possible pairs  $(H_n, a_n)$  grows as  $N \cdot n$  (linearly in  $n$ ) where  $N$  is the fixed number of environmental states  $H^i$ , rather than  $n^2$  (quadratically in  $n$ ) as in Wilson et al. (2010).<sup>1</sup>

**3.1 Symmetric Two-State Process.** We first derive a recursive equation for the probability of two alternatives,  $H_n \in \{H^\pm\}$ , in a changing environment, where the change process is memoryless and the change rate,  $\epsilon := P(H_n = H^\mp | H_{n-1} = H^\pm)$ , is symmetric and initially unknown to the observer (see Figure 1A). The most probable choice given the observations up to a time,  $t_n$ , can be obtained from the log of the posterior odds ratio  $L_n = \log \left( \frac{P_n(H_n = H^+)}{P_n(H_n = H^-)} \right)$ . The sign of  $L_n$  indicates which option is more likely, and its magnitude indicates the strength of this evidence (Bogacz et al., 2006; Gold & Shadlen, 2007). Old evidence should be discounted according to the inferred environmental volatility. Since this is unknown, an ideal observer computes a probability distribution for the change rate,  $\epsilon$  (see Figure 1C), along with the probability of environmental states.

Let  $a_n$  be the number of change points and  $b_n = n - 1 - a_n$  the count of non-change-points between times  $t_1$  and  $t_n$  ( $n = 1, 2, \dots$ ) (see Figure 1B).

<sup>1</sup>The algorithm in Wilson et al. (2010) requires estimating the run length  $r_n$  and change-point count  $a_n$ , so the dimension of the pair  $(r_n, a_n)$  grows like  $n^2$ .

The process  $\{a_n\}_{n \geq 1}$  is a pure birth process with birth rate  $\epsilon$ . The observer assumes no changes prior to the start of observation,  $P(a_1 = 0) = 1$ , and must make at least two observations,  $\xi_1$  and  $\xi_2$ , to detect a change.

To develop an iterative equation for the joint conditional probability density,  $P_n(H_n, a_n)$ , given the  $n$  observations  $\xi_{1:n}$ , we begin by marginalizing over these quantities at the time of the previous observation,  $t_{n-1}$ , for  $n > 1$  (see section A.1 for details):

$$\begin{aligned}
 P_n(H_n, a_n) = & \\
 \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} P(\xi_n | H_n) & \sum_{H_{n-1}=H^\pm} \sum_{a_{n-1}=0}^{n-2} P(H_n, a_n | H_{n-1}, a_{n-1}) P_{n-1}(H_{n-1}, a_{n-1}).
 \end{aligned}
 \tag{3.1}$$

With two choices, we have the following relationships for all  $n > 1$ :

$$H_n = H_{n-1} \Leftrightarrow a_n = a_{n-1}, \quad \text{and} \quad H_n \neq H_{n-1} \Leftrightarrow a_n = a_{n-1} + 1. \tag{3.2}$$

The term  $P(H_n, a_n | H_{n-1}, a_{n-1})$  in equation 3.1 is therefore nonzero only if either,  $H_{n-1} = H_n$ , and  $a_{n-1} = a_n$ , or  $H_{n-1} \neq H_n$  and  $a_{n-1} = a_n - 1$ . If the system is in the joint state  $(H_{n-1}, a_{n-1})$  at  $t_{n-1}$ , then at  $t_n$ , it can either transition to  $(H_n \neq H_{n-1}, a_n = a_{n-1} + 1)$  or remain at  $(H_n = H_{n-1}, a_n = a_{n-1})$ . This observation is central to the message-passing algorithm described in Adams and MacKay (2007) and Wilson et al. (2010), with probability mass flowing from lower to higher values of  $a$  according to a pure birth process (see Figure 2A). We can thus simplify equation 3.1, leaving only two terms in the double sum. Writing  $P_n(H^\pm, a)$  for  $P_n(H_n = H^\pm, a_n = a)$ , and similarly for any conditional probabilities, we have for  $n > 1$ :

$$\begin{aligned}
 P_n(H^\pm, a) = & \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^\pm(\xi_n) [P(H^\pm, a | H_{n-1} = H^\pm, a_{n-1} = a) \\
 & \cdot P_{n-1}(H^\pm, a) + P(H^\pm, a | H_{n-1} = H^\mp, a_{n-1} = a - 1) \\
 & \cdot P_{n-1}(H^\mp, a - 1)].
 \end{aligned}
 \tag{3.3}$$

We must also specify initial conditions at time  $t_1$  and boundary values when  $a \in \{0, n - 1\}$  for these equations. At  $t_1$  we have  $P(a_1 = 0) = 1$ . Therefore,

$$P_1(H^\pm, 0) = \frac{1}{P(\xi_1)} f^\pm(\xi_1) P_0(H^\pm), \tag{3.4}$$

and  $P_1(H^\pm, a) = 0$  for  $a \neq 0$ . Here  $P_0(H^\pm)$  is the prior over the two choices, which we typically take to be uniform so  $P_0(H^+) = P_0(H^-)$ . The probability

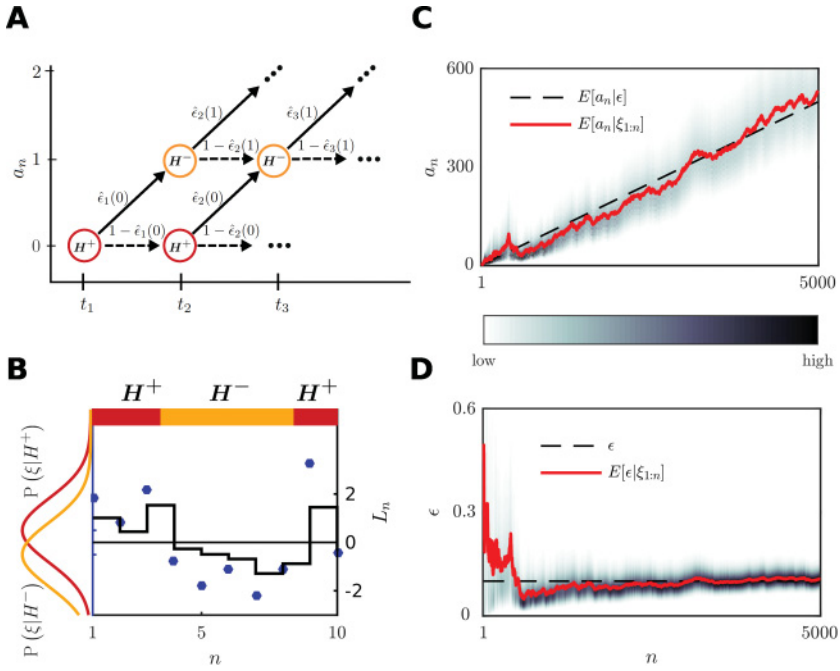

Figure 2: Inference of the states,  $H^\pm$ , and change rate,  $\epsilon$ . (A) The joint posterior probability,  $P_n(H^\pm, a)$ , is propagated along a directed graph according to equation 3.14. Only paths corresponding to the initial condition  $(H_1, a_1) = (H^+, 0)$  are shown. (B) A sample sequence of environmental states (color bar, top) together with the first 10 observations  $\xi_1, \dots, \xi_{10}$  (blue dots), for  $\epsilon = 0.1$ . Superimposed in black (right y-axis) is the log-posterior odds ratio  $L_n$  as a function of time. (C) Evolution of the posterior over  $a_n$  (gray scale). The posterior mean (red) converges to the expected number of change points  $\epsilon(n - 1)$  (dashed line). (D) Evolution of the posterior over the change rate  $\epsilon$  (gray scale). The posterior mean (red) converges to the true value (dashed line), and the variance diminishes with the number of observations.

$P(\xi_1)$  is unknown to the observer. However, similar to the ratio  $\frac{P(\xi_{1:n-1})}{P(\xi_{1:n})}$  in equation 3.3,  $P(\xi_1)$  acts as a normalization constant and does not appear in the posterior odds ratio,  $R_n$  (see equation 3.15). Finally, at all future times  $n > 1$ , we have separate equations at the boundaries,

$$P_n(H^\pm, 0) = \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^\pm(\xi_n) P(H^\pm, 0 | H_{n-1} = H^\pm, a_{n-1} = 0) P_{n-1}(H^\pm, 0) \tag{3.5}$$

and

$$\begin{aligned}
 P_n(H^\pm, n-1) &= \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^\pm(\xi_n) P(H^\pm, n-1 | H_{n-1} = H^\mp, a_{n-1} = n-2) \\
 &\quad \times P_{n-1}(H^\mp, n-2).
 \end{aligned}
 \tag{3.6}$$

We next compute  $P(H_n, a_n | H_{n-1}, a_{n-1})$  in equation 3.1, with  $n > 1$ , by marginalizing over all possible transition rates  $\epsilon \in [0, 1]$ :

$$P(H_n, a_n | H_{n-1}, a_{n-1}) = \int_0^1 P(H_n, a_n | \epsilon, H_{n-1}, a_{n-1}) P(\epsilon | H_{n-1}, a_{n-1}) d\epsilon.
 \tag{3.7}$$

Note that  $P(\epsilon | H_{n-1}, a_{n-1}) = P(\epsilon | a_{n-1})$ , so we need the distribution of  $\epsilon$ , given  $a_{n-1}$  change points, for all  $n > 1$ . We assume that prior to any change point observations—that is, at time  $t_1$ —the rates follow a beta distribution with hyperparameters  $a_0, b_0 > 0$  (see also sections 3.1 and 3.2 in Wilson et al., 2010),

$$P_0(\epsilon) = \beta(\epsilon; a_0, b_0) := \frac{\epsilon^{a_0-1} (1-\epsilon)^{b_0-1}}{B(a_0, b_0)},$$

where  $\beta$  denotes the probability density of the associated beta distribution and  $B(x, y) := \int_0^1 \epsilon^{x-1} (1-\epsilon)^{y-1} d\epsilon$  is the beta function. For any  $n > 1$ , the random variable  $a_n | \epsilon$  follows a binomial distribution with parameters  $(n-1, \epsilon)$ , for which the beta distribution is a conjugate prior. The posterior over the change rate when the change-point count is known at time  $n > 1$  is therefore

$$\epsilon | a_n \sim \text{Beta}(a_0 + a_n, b_0 + b_n).
 \tag{3.8}$$

For simplicity, we assume that prior to any observations, the probability over the transition rates is uniform,  $P_0(\epsilon) = 1$ , for all  $\epsilon \in [0, 1]$ , and therefore  $a_0 = b_0 = 1$  (see Figure 1C).

We now return to equation 3.7 and use the definition of the transition rate,  $\epsilon$ , (see Figure 1) to find

$$P(H_n, a_n | \epsilon, H_{n-1}, a_{n-1}) = \begin{cases} 1 - \epsilon, & \& : H_n = H_{n-1} \ \& \ a_n = a_{n-1}, \\ \epsilon, & \& : H_n \neq H_{n-1} \ \& \ a_n = a_{n-1} + 1, \\ 0, & \& : \text{otherwise.} \end{cases}
 \tag{3.9}$$

Equation 3.7 can therefore be rewritten using two integrals, depending on the values of  $(H_n, a_n)$  and  $(H_{n-1}, a_{n-1})$ ,

$$P(H^\pm, a|H_{n-1} = H^\pm, a_{n-1} = a) = \int_0^1 (1 - \epsilon)\beta(\epsilon; a_{n-1} + 1, b_{n-1} + 1)d\epsilon, \tag{3.10}$$

and similarly for  $P(H^\pm, a|H_{n-1} = H^\mp, a_{n-1} = a - 1)$ .

The mean of the beta distribution, for  $n > 1$ , can be expressed in terms of its two parameters:

$$\hat{\epsilon}_{n-1}(a_{n-1}) := \mathbb{E}[\epsilon|a_{n-1}] = \frac{a_{n-1} + 1}{a_{n-1} + b_{n-1} + 2}. \tag{3.11}$$

We denote this expected value by  $\hat{\epsilon}_{n-1}(a_{n-1})$  as it represents a point estimate of the change rate  $\epsilon$  at time  $t_{n-1}$  when the change-point count is  $a_{n-1}$ ,  $n > 1$ . Since  $a_{n-1} + b_{n-1} = n - 2$ , we have

$$\hat{\epsilon}_{n-1}(a_{n-1}) = \frac{a_{n-1} + 1}{n}. \tag{3.12}$$

The expected transition rate,  $\hat{\epsilon}_{n-1}(a_{n-1})$ , is thus determined by the ratio between the previous change-point count and the number of time steps,  $n$ . Leaving  $a_0$  and  $b_0$  as parameters in the prior gives  $\hat{\epsilon}_{n-1}(a_{n-1}) = (a_{n-1} + a_0)/(n - 2 + a_0 + b_0)$ . Using the definition in equation 3.12, it follows from equation 3.10 that

$$P(H^\pm, a|H_{n-1} = H^\pm, a_{n-1} = a) = 1 - \hat{\epsilon}_{n-1}(a), \tag{3.13a}$$

$$P(H^\pm, a|H_{n-1} = H^\mp, a_{n-1} = a - 1) = \hat{\epsilon}_{n-1}(a - 1). \tag{3.13b}$$

Equations 3.13a and 3.13b, illustrated in Figure 2A, can in turn be substituted into equation 3.3 to yield, for all  $n > 1$ :

$$P_n(H^\pm, a) = \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^\pm(\xi_n) [(1 - \hat{\epsilon}_{n-1}(a)) \cdot P_{n-1}(H^\pm, a) + \hat{\epsilon}_{n-1}(a - 1) \cdot P_{n-1}(H^\mp, a - 1)]. \tag{3.14}$$

The initial conditions and boundary equations for this recursive probability update have already been described in equations 3.4 to 3.6. Equation 3.14 is the equivalent of equation 3 in Adams and MacKay (2007), and equation 3.7 in Wilson et al. (2010). However, here the observer does not need to

estimate the length of the interval since the last change point. We demonstrate the inference process defined by equation 3.14 in Figure 2.

The observer can compute the posterior odds ratio by marginalizing over the change-point count:

$$R_n := \frac{P_n(H^+)}{P_n(H^-)} = \frac{\sum_{a=0}^{n-1} P_n(H^+, a)}{\sum_{a=0}^{n-1} P_n(H^-, a)}. \quad (3.15)$$

Here  $\log(R_n) = L_n > 0$  implies that  $H_n = H^+$  is more likely than  $H_n = H^-$  (see Figure 2B). Note that  $P(\xi_{1:n-1})/P(\xi_{1:n})$  and  $1/P(\xi_1)$  need not be known to the observer to obtain the most likely choice.

A posterior distribution of the transition rate  $\epsilon$  can also be derived from equation 3.14 by marginalizing over  $(H_n, a_n)$ ,

$$P_n(\epsilon) = \sum_{s=\pm} \sum_{a=0}^{n-1} P(\epsilon|a_n = a) P_n(H^s, a), \quad (3.16)$$

where  $P(\epsilon|a_n)$  is given by the beta distribution prior, equation 3.8. The expected rate is therefore

$$\begin{aligned} \bar{\epsilon} &:= \int_0^1 \epsilon P_n(\epsilon) d\epsilon = \sum_{s=\pm} \sum_{a_n=0}^{n-1} \int_0^1 \epsilon P(\epsilon|a_n) P_n(H^s, a_n) d\epsilon \\ &= \sum_{s=\pm} \sum_{a_n=0}^{n-1} \frac{a_n + 1}{n + 1} P_n(H^s, a_n). \end{aligned} \quad (3.17)$$

Explicit knowledge of the transition rate,  $\epsilon$ , is not used in the inference process described by equation 3.14. However, computing it allows us to evaluate how the observer's estimate converges to the true transition rate (see Figure 2D). We will also relate this estimate to the coupling strength between neural populations in the model described in section 6.

We conjecture that when measurements are noisy, the variance of the distribution  $P_n(\epsilon)$  does not converge to a point mass at the true rate,  $\epsilon$ , in the limit of infinitely many observations,  $n \rightarrow \infty$ ; that is, the estimate of  $\epsilon$  is not consistent. As we have shown, to infer the rate, we need to infer the parameter of a Bernoulli variable. It is easy to show that the posterior over this parameter converges to a point mass at the actual rate value if the probability of misclassifying the state is known to the observer (Djuric & Huang, 2000). However, when the misclassification probability is not known, the variance of the posterior remains positive even in the limit of infinitely many observations. In our case, when measurements are noisy, the observer does not know the exact number of change points at a finite

Figure 3: The performance of the inference algorithm. (A) Performance under the interrogation paradigm measured as the percentage of correct responses at the interrogation time. Here and in the next panel,  $\epsilon = 0.05$ , and  $\text{SNR} = 1$ . The black curve represents the performance of an ideal observer who infers the change rate from measurements. The green curves represent the performance of observers who assume a fixed change rate (0.3, 0.15, 0.05, 0.03 from darker to lighter; see equation 2.1). The solid green line corresponds to an observer who assumes the true rate and the dashed lines to erroneous rates. (B) The green curve represents the performance at interrogation time  $t_{300}$  of an observer who assumes a fixed change rate. The red star marks the maximum of this curve, corresponding to the true change rate  $\epsilon = 0.05$ . The horizontal black curves represent the performance at times  $t_{40}$ ,  $t_{100}$ ,  $t_{200}$ ,  $t_{300}$  (from bottom to top) of the observer who learns the change rate. (C) The accuracy as a function of the average threshold hitting time in the free response protocol. Here  $\epsilon = 0.1$ , and  $\text{SNR} = 0.75$ . See section A.2 for details on numerical simulations. See also Figure 3 in Veliz-Cuba et al. (2016).

time. Hence, the observer does not know exactly how to weight previous observations to make an inference about the current state. As a result, the probability of misclassifying the current state may not be known. We conjecture that this implies that even in the limit  $n \rightarrow \infty$ , the posterior over  $\epsilon$  has positive variance (see Figure 2D).

In Figure 3, we compare the performance of this algorithm in three cases: when the observer knows the true rate (point mass prior over the true rate  $\epsilon$ ), when the observer assumes a wrong rate (point mass prior over an erroneous  $\epsilon$ ), and when the observer learns the rate from measurements (flat prior over  $\epsilon$ ). We define performance as the probability of a correct decision.

Under the interrogation protocol, the observer infers the state of the environment at a fixed time. As expected, performance increases with interrogation time and is highest if the observer uses the true rate (see Figure 3A and equation 2.1). Performance plateaus quickly when the observer assumes a fixed rate and more slowly if the rate is learned. The performance of observers who learn the rate slowly increases toward that of observers who know the true rate. In Figure 3B, we present the performance of the

unknown-rate algorithm at four different times ( $t_{40}, t_{100}, t_{200}, t_{300}$ ) and compare it to the asymptotic values with different assumed rates (green curves).

Note that an observer who assumes an incorrect change rate can still perform near optimally (e.g., curve for 0.03 in Figure 3A), especially when the signal-to-noise ratio (SNR) is quite high. The SNR is the difference in means of the likelihoods divided by their common standard deviation. Change rate inference is more effective at lower SNR values, in which case multiple observations are needed for an accurate estimate of the present state. However, at very low SNR values, the observer will not be able to substantially reduce uncertainty about the change rate, resulting in high uncertainty about the state.

In the free response protocol, the observer makes a decision when the log-odds ratio reaches a predefined threshold. In Figure 3C, we present simulation results for this protocol in a format similar to Figure 3A, with empirical performance as a function of average hitting time. Each performance level corresponds to unique log-odds threshold. Similar to the interrogation protocol (see Figure 3A), the performance of the free response protocol saturates much more quickly for an observer who fixes the change rate estimate than one that infers this rate over time.

**3.2 Symmetric Multistate Process.** We next consider evidence accumulation in an environment with an arbitrary number of states,  $\{H^1, H^2, \dots, H^N\}$ , with symmetric transition probabilities,  $\epsilon^{ij} \equiv \text{constant}$ , whenever  $i \neq j$ . We define  $\epsilon := (N - 1)\epsilon^{ij}$  for any  $i \neq j$ , so that the probability of remaining in the same state becomes  $\epsilon^{ii} = 1 - \epsilon$ , for all  $i = 1, \dots, N$ . The symmetry in transition rates means that an observer still needs only to track the total number of change points,  $a_n$ , as in section 3.1.

Equations 3.1 and 3.2 remain valid with  $N$  possible choices,  $\{H^1, \dots, H^N\}$ . When  $n > 1$ , the double sum in equation 3.1 simplifies to

$$P_n(H^i, a) = \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^i(\xi_n) \left[ P(H^i, a | H_{n-1} = H^i, a_{n-1} = a) \cdot P_{n-1}(H^i, a) + \sum_{j \neq i} P(H^j, a | H_{n-1} = H^j, a_{n-1} = a - 1) \cdot P_{n-1}(H^j, a - 1) \right].$$

As in section 3.1, we have  $P_1(H^i, 0) = f^i(\xi_1)P_0(H^i)/P(\xi_1)$  and  $P_1(H^i, a_1) = 0$  for  $a_1 \neq 0$ , where  $P_0(H^i)$  describes the observer's belief prior to any observations. At all future times,  $n > 1$ , we have at the boundaries for all  $i = 1, \dots, N$

$$P_n(H^i, 0) = \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^i(\xi_n) P(H^i, 0 | H_{n-1} = H^i, a_{n-1} = 0) P_{n-1}(H^i, 0),$$

and

$$P_n(H^i, n - 1) = \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^i(\xi_n) \sum_{j \neq i} P(H^j, n - 1 | H_{n-1} = H^j, a_{n-1} = n - 2) \times P_{n-1}(H^j, n - 2).$$

Equation 3.7 remains unchanged, and we still have  $P(\epsilon | H_{n-1}, a_{n-1}) = P(\epsilon | a_{n-1})$ . Furthermore, assuming a beta prior on the change rate, equation 3.8, remains valid, and equation 3.9 is replaced by

$$P(H_n, a_n | \epsilon, H_{n-1}, a_{n-1}) = \begin{cases} 1 - \epsilon & H_n = H_{n-1} \ \& \ a_n = a_{n-1}, \\ \epsilon / (N - 1) & H_n \neq H_{n-1} \ \& \ a_n = a_{n-1} + 1, \\ 0 & \text{otherwise.} \end{cases}$$

The integral from equation 3.7 gives, once again, the mean of the beta distribution,  $\hat{\epsilon}_{n-1}(a)$ , defined in equations 3.11 and 3.12. As in section 3.1,  $\hat{\epsilon}_{n-1}(a_{n-1})$  is a point estimate of the change rate  $\epsilon$  at time  $t_{n-1}$  when the change-point count is  $a_{n-1}$ . We have

$$P(H_n, a_n | H_{n-1}, a_{n-1}) = \begin{cases} 1 - \hat{\epsilon}_{n-1}(a_n), & \& : H_n = H_{n-1} \ \& \ a_n = a_{n-1}, \\ \hat{\epsilon}_{n-1}(a_n - 1) / (N - 1), & \& : H_n \neq H_{n-1} \ \& \ a_n = a_{n-1} + 1, \\ 0, & \& : \text{otherwise,} \end{cases} \quad (3.18)$$

and the main probability update equation is now

$$P_n(H^i, a) = \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^i(\xi_n) \left[ (1 - \hat{\epsilon}_{n-1}(a_n)) \cdot P_{n-1}(H^i, a) + \frac{\hat{\epsilon}_{n-1}(a_n - 1)}{N - 1} \sum_{j \neq i} P_{n-1}(H^j, a - 1) \right].$$

The observer can infer the most likely state of the environments by computing the index that maximizes the posterior probability, marginalizing over all change-point counts,

$$\hat{i} = \operatorname{argmax}_i P_n(H^i) = \operatorname{argmax}_i \left( \sum_{a=0}^{n-1} P_n(H^i, a) \right).$$

The observer can also compute the posterior probability  $P_n(\epsilon)$  of the transition rate  $\epsilon$  by marginalizing over all states  $H_n$  and change-point counts  $a_n$ , as in equation 3.16. Furthermore, a point estimate of  $\epsilon$  is given by the mean of the posterior after marginalizing, as in equation 3.17.

#### 4 Environments with Asymmetric Transition Rates

In this section, we depart from the framework of Adams and MacKay (2007) and Wilson et al. (2010) and consider unequal transition rates between states. This includes the possibility that some transitions are not allowed. We consider an arbitrary number,  $N$ , of states with unknown transition rates,  $\epsilon^{ij}$ , between them. The switching process between the states is again memoryless, so that  $H_n$  is a stationary, discrete-time Markov chain with finite state space,  $\Omega := \{H^1, \dots, H^N\}$ . We write the (unknown) transition matrix for this chain as a left stochastic matrix,

$$\epsilon := \begin{pmatrix} \epsilon^{11} & \dots & \epsilon^{1N} \\ \vdots & \ddots & \vdots \\ \epsilon^{N1} & \dots & \epsilon^{NN} \end{pmatrix},$$

where  $\epsilon^{ij} = P(H_n = H^i | H_{n-1} = H^j)$ , with  $i, j \in \{1, \dots, N\}$ . We denote by  $\epsilon^i$  the  $i$ th column of the matrix  $\epsilon$ , and similarly for other matrices. Each such column sums to 1. We define the change-point counts matrix at time  $t_n$  as

$$\mathbf{a}_n := \begin{pmatrix} a_n^{11} & \dots & a_n^{1N} \\ \vdots & \ddots & \vdots \\ a_n^{N1} & \dots & a_n^{NN} \end{pmatrix},$$

where  $a_n^{ij}$  is the number of transitions from state  $j$  to state  $i$  up to time  $t_n$ . There can be a maximum of  $n - 1$  transitions at time  $t_n$ . For a fixed  $n \geq 1$ , all entries in  $\mathbf{a}_n$  are nonnegative and sum to  $n - 1$ , that is,  $\sum_{i,j} a_n^{ij} = n - 1$ . As in the symmetric case, the change-point matrix at time  $t_1$  must be the zero matrix,  $\mathbf{a}_1 = 0$ .

We will show that our inference algorithm assigns positive probability only to change-point matrices that correspond to possible transition paths between the states  $\{H^1, \dots, H^N\}$ . Many nonnegative integer matrices with entries that sum to  $n - 1$  are not possible change-point matrices  $\mathbf{a}_n$ . A combinatorial argument shows that when  $N = 2$ , the number of possible pairs,  $(H_n, \mathbf{a}_n)$ , grows quadratically with the number of steps,  $n$ , to leading order. It can also be shown that the growth is polynomial for  $N > 2$ , although we do not know the growth rate in general (see Figure 4B). An ideal observer

has to assign a probability of each of these states, which is much more demanding than in the symmetric rate case where the number of possible states grows linearly in  $n$ .

We next derive an iterative equation for  $P_n(H_n, \mathbf{a}_n)$ , the joint probability of the state  $H_n$ , and an allowable combination of the  $N(N - 1)$  change-point counts (off-diagonal terms of  $\mathbf{a}_n$ ) and  $N$  non-change-point counts (diagonal terms of  $\mathbf{a}_n$ ). The derivation is similar to the symmetric case. For  $n > 1$ , we first marginalize over  $H_{n-1}$  and  $\mathbf{a}_{n-1}$ ,

$$P_n(H_n, \mathbf{a}_n) = \frac{1}{P(\xi_{1:n})} \sum_{H_{n-1}, \mathbf{a}_{n-1}} P(\xi_{1:n} | H_n, H_{n-1}, \mathbf{a}_n, \mathbf{a}_{n-1}) P(H_n, H_{n-1}, \mathbf{a}_n, \mathbf{a}_{n-1}),$$

where the sum is over all  $H_{n-1} \in \{H^1, \dots, H^N\}$  and possible values of the change-point matrix,  $\mathbf{a}_{n-1}$ .

Using  $P(H_n, H_{n-1}, \mathbf{a}_n, \mathbf{a}_{n-1}) = P(H_n, \mathbf{a}_n | H_{n-1}, \mathbf{a}_{n-1}) P(H_{n-1}, \mathbf{a}_{n-1})$ , and applying Bayes' rule to write

$$P(\xi_{1:n-1} | H_{n-1}, \mathbf{a}_{n-1}) P(H_{n-1}, \mathbf{a}_{n-1}) = P(H_{n-1}, \mathbf{a}_{n-1} | \xi_{1:n-1}) P(\xi_{1:n-1})$$

gives

$$P_n(H_n, \mathbf{a}_n) = \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} P(\xi_n | H_n) \sum_{H_{n-1}, \mathbf{a}_{n-1}} P_{n-1}(H_{n-1}, \mathbf{a}_{n-1}) \times P(H_n, \mathbf{a}_n | H_{n-1}, \mathbf{a}_{n-1}). \tag{4.1}$$

We compute the conditional probability  $P(H_n, \mathbf{a}_n | H_{n-1}, \mathbf{a}_{n-1})$  by marginalizing over all possible transition matrices,  $\epsilon$ . To do so, we relate the probabilities of  $\epsilon$  and  $\mathbf{a}$ . Note that if the observer assumes the columns  $\epsilon^j$  are independent prior to any observations, then the exit rates conditioned on the change-point counts,  $\epsilon^j | \mathbf{a}_n^j$ , are independent for all states,  $j = 1, \dots, N$ .

To motivate the derivation, we first consider a single state,  $j = 1$ , and assume that the environmental state has been observed perfectly over  $T > 1$  time steps, but the transition rates are unknown. Therefore, all  $\mathbf{a}_n^1$  are known to the observer ( $1 \leq n \leq T$ ), but the  $\epsilon^1$  are not. The state of the system at time  $n + 1$ , given that it was in state  $H^1$  at time  $n$ , is a categorical random variable, and  $P(H_{n+1} = H^i | H_n = H^1) = \epsilon^{i1}$ , for  $1 \leq n \leq T - 1$ . The observed transitions  $H^1 \mapsto H^i$  are independent samples from a categorical distribution with unknown parameters  $\epsilon^1$ .

The conjugate prior to the categorical distribution is the Dirichlet distribution, and we therefore use it as a prior on the change-point probabilities.

For simplicity, we again assume a flat prior over  $\epsilon^1$ , that is,  $P(\epsilon^1) = \chi_S(\epsilon^1)$ , where  $\chi_S$  is the indicator function on the standard  $(N - 1)$ -simplex,  $S$ .

Denote by  $D$  the sequence of states that the environment transitioned to at time  $n + 1$  whenever it was in state  $H^1$  at time  $n$ , for all  $1 \leq n \leq T - 1$ . Therefore,  $D$  is a sequence of states from the set  $\{H^1, \dots, H^N\}$ . By definition,  $P(D|\epsilon^1) = \prod_{i=1}^N (\epsilon^{i1})^{\sum_{n=1}^{T-1} \chi(H_{n+1}=H^i, H_n=H^1)}$ , where  $\chi(H_{n+1} = H^i, H_n = H^1)$  is the indicator function, which is unity only when  $H_{n+1} = H^i$  and  $H_n = H^1$  and zero otherwise. Equivalently, we can write  $P(\mathbf{a}_T^1|\epsilon^1) = \prod_{i=1}^N (\epsilon^{i1})^{a_T^1}$ , since  $\mathbf{a}_T^1 = \sum_{n=1}^{T-1} \chi(H_{n+1} = H^i, H_n = H^1)$ . For general  $n > 1$ , the posterior distribution for the transition probabilities  $\epsilon^1$  given the change-point vector  $\mathbf{a}_n^1$  is then

$$P(\epsilon^1|\mathbf{a}_n^1) = \frac{\Gamma\left(\sum_{i=1}^N (a_n^{i1} + 1)\right)}{\prod_{i=1}^N \Gamma(a_n^{i1} + 1)} \prod_{i=1}^N (\epsilon^{i1})^{a_n^{i1}} = \text{dir}(\epsilon^1; \mathbf{a}_n^1 + \mathbf{1}).$$

Here  $\mathbf{1} = (1, \dots, 1)^T$ , so  $\mathbf{a}_n^1 + \mathbf{1}$  should be interpreted as the vector with entries  $(a_n^{i1} + 1)_{i=1}^N$ ,  $\Gamma(x)$  is the gamma function, and  $\text{dir}(\epsilon^1; \mathbf{a}_n^1 + \mathbf{1})$  the probability density function of the  $N$ -dimensional Dirichlet distribution,  $\text{Dir}(\mathbf{a}_n^1 + \mathbf{1})$ .

The same argument applies to all initial states,  $H^j$ ,  $j \in \{1, \dots, N\}$ . We assume that the transition rates are conditionally independent, so that

$$P(\epsilon|\mathbf{a}_n) = \prod_{j=1}^N \text{dir}(\epsilon^j; \mathbf{a}_n^j + \mathbf{1}) = \prod_{j=1}^N \frac{\Gamma\left(\sum_{i=1}^N (a_n^{ij} + 1)\right)}{\prod_{i=1}^N \Gamma(a_n^{ij} + 1)} \prod_{k=1}^N (\epsilon^{kj})^{a_n^{kj}}. \quad (4.2)$$

Using this observation, the transition probability between two states can be computed by marginalizing over all possible transition matrices,  $\epsilon$ , conditioned on  $\mathbf{a}_{n-1}$ ,

$$\begin{aligned} &P(H_n, \mathbf{a}_n | H_{n-1}, \mathbf{a}_{n-1}) \\ &= \int_{\mathcal{M}} P(H_n, \mathbf{a}_n | \epsilon, H_{n-1}, \mathbf{a}_{n-1}) P(\epsilon | H_{n-1}, \mathbf{a}_{n-1}) d\epsilon \\ &= \int_S \dots \int_S P(H_n, \mathbf{a}_n | \epsilon^1, \dots, \epsilon^N, H_{n-1}, \mathbf{a}_{n-1}) \\ &\quad \times \text{dir}(\epsilon^1; \mathbf{a}_{n-1}^1 + \mathbf{1}) \times \dots \times \text{dir}(\epsilon^N; \mathbf{a}_{n-1}^N + \mathbf{1}) d\epsilon^1 \dots d\epsilon^N, \quad (4.3) \end{aligned}$$

where  $\mathcal{M}$  represents the space of all  $N \times N$  left stochastic matrices and  $S$  is the  $N - 1$ -dimensional simplex of  $\epsilon^j \in [0, 1]^N$  such that  $\sum_{i=1}^N \epsilon^{ij} = 1$ .

Let  $\delta^{ij}$  be the  $N \times N$  matrix containing a 1 as its  $ij$ th entry, and 0 everywhere else. For all  $i, j \in \{1, \dots, N\}$  we have

$$P(H_n = H^i, \mathbf{a}_n | \boldsymbol{\epsilon}, H_{n-1} = H^j, \mathbf{a}_{n-1}) = \begin{cases} \epsilon^{ij} & \text{if } \mathbf{a}_n = \mathbf{a}_{n-1} + \delta^{ij}, \\ 0 & \text{otherwise.} \end{cases} \quad (4.4)$$

Implicit in equation 4.4 is the requirement that the environment must have been in state  $H_{n-1} = H^j$  in order for the transition  $H^j \mapsto H^i$  to have occurred between  $t_{n-1}$  and  $t_n$ . This will ensure that the change-point matrices  $\mathbf{a}_n$  that are assigned nonzero probability correspond to admissible paths through the states  $\{H^1, \dots, H^N\}$ . Applying equation 4.4, we can compute the integrals in equation 4.3 for all pairs  $(i, j)$ . We let  $\hat{\epsilon}_{n-1}^{ij}(\mathbf{a}_{n-1}) := P(H_n = H^i, \mathbf{a}_n = \mathbf{a}_{n-1} + \delta^{ij} | H_{n-1} = H^j, \mathbf{a}_{n-1})$  to simplify notation and find

$$\begin{aligned} \hat{\epsilon}_{n-1}^{ij}(\mathbf{a}_{n-1}) &= \int_S \dots \int_S \epsilon^{ij} \prod_{k=1}^N \text{dir}(\boldsymbol{\epsilon}^k; \mathbf{a}_{n-1}^k + \mathbf{1}) d\boldsymbol{\epsilon}^1 \dots d\boldsymbol{\epsilon}^N \\ &= \int_S \epsilon^{ij} \text{dir}(\boldsymbol{\epsilon}^j; \mathbf{a}_{n-1}^j + \mathbf{1}) d\boldsymbol{\epsilon}^j \prod_{k \neq j} \int_S \text{dir}(\boldsymbol{\epsilon}^k; \mathbf{a}_{n-1}^k + \mathbf{1}) d\boldsymbol{\epsilon}^k \\ &= \int_S \epsilon^{ij} \text{dir}(\boldsymbol{\epsilon}^j; \mathbf{a}_{n-1}^j + \mathbf{1}) d\boldsymbol{\epsilon}^j = \frac{a_{n-1}^{ij} + 1}{N + \sum_{k=1}^N a_{n-1}^{kj}}. \end{aligned} \quad (4.5)$$

As in the point estimate of the rate  $\hat{\epsilon}_{n-1}(\mathbf{a}_{n-1})$  in equation 3.12, each  $\hat{\epsilon}_{n-1}^{ij}(\mathbf{a}_{n-1})$  is a ratio containing the number of  $H^j \mapsto H^i$  transitions in the numerator and the total number of transitions out of the  $j$ th state in the denominator. Thus, the estimated transition rate  $\hat{\epsilon}_{n-1}^{ij}(\mathbf{a}_{n-1})$  increases with the number of transitions  $H^j \mapsto H^i$  in a given interval  $\{1, \dots, n\}$ . Furthermore, each column sums to unity;

$$\sum_{i=1}^N \hat{\epsilon}_{n-1}^{ij}(\mathbf{a}_{n-1}) = \frac{\sum_{i=1}^N (a_{n-1}^{ij} + 1)}{N + \sum_{k=1}^N a_{n-1}^{kj}} = \frac{N + \sum_{i=1}^N a_{n-1}^{ij}}{N + \sum_{k=1}^N a_{n-1}^{kj}} = 1,$$

so the point estimates  $\hat{\epsilon}_{n-1}^{ij}(\mathbf{a}_{n-1})$  for the transition rates out of each state  $j$  provide an empirical probability mass function along each column. However, as in the symmetric case, these estimates are biased toward the interior of the domain. This is a consequence of the hyperparameters we have chosen for our prior density,  $\text{dir}(\boldsymbol{\epsilon}; \mathbf{a}_0 + \mathbf{1})$ .

Therefore, for  $n > 1$ , the probability update equation in the case of asymmetric transition rates, equation 4.1, is given by

$$\begin{aligned} P_n(H_n = H^i, \mathbf{a}_n) &= \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^i(\xi_n) \sum_{j=1}^N \hat{\epsilon}_{n-1}^{ij}(\mathbf{a}_n - \delta^{ij}) P_{n-1}(H_{n-1} = H^j, \mathbf{a}_n - \delta^{ij}). \end{aligned} \quad (4.6)$$

The point estimates of the transition rates,  $\hat{\epsilon}_{n-1}^{ij}(\mathbf{a}_{n-1} = \mathbf{a}_n - \delta^{ij})$ , are defined in equation 3.5. As before,  $P_1(H^i, \mathbf{a}_1 = 0) = f^i(\xi_1)P_0(H^i)/P(\xi_1)$  and  $P_1(H^i, \mathbf{a}_1) = 0$  for any  $\mathbf{a}_1 \neq 0$ . At future times, it is only possible to obtain change-point matrices  $\mathbf{a}_n$  whose entries sum to  $\sum_{i,j} a_n^{ij} = n - 1$ ; the change-point matrices  $\mathbf{a}_n$  and  $\mathbf{a}_{n-1}$  must be related as  $\mathbf{a}_n = \mathbf{a}_{n-1} + \delta^{ij}$ , as noted in equation 4.4. This considerably reduces the number of terms in the sum in equation 4.6.

The observer can find the most likely state of the environment by maximizing the posterior probability after marginalizing over the change-point counts  $\mathbf{a}_n$ ,

$$\hat{i} = \operatorname{argmax}_i P_n(H^i) = \operatorname{argmax}_i \left( \sum_{\mathbf{a}_n} P_n(H^i, \mathbf{a}_n) \right).$$

The transition rate matrix can also be computed by marginalizing across all possible states,  $H_n$ , and change-point count matrices,  $\mathbf{a}_n$ ,

$$P_n(\epsilon) = \sum_{s=1}^N \sum_{\mathbf{a}_n} P(\epsilon | \mathbf{a}_n) P_n(H^s, \mathbf{a}_n),$$

where  $P(\epsilon | \mathbf{a}_n)$  is the product of probability density functions,  $\operatorname{dir}(\epsilon^j; \mathbf{a}_n^j + 1)$ , given in equation 4.2. The mean of this distribution is given by

$$\begin{aligned} \bar{\epsilon} &= \int_{\mathcal{M}} \epsilon P_n(\epsilon) d\epsilon = \sum_{s=1}^N \sum_{\mathbf{a}_n} P_n(H^s, \mathbf{a}_n) \int_{\mathcal{M}} \epsilon P(\epsilon | \mathbf{a}_n) d\epsilon \\ &= \sum_{s=1}^N \sum_{\mathbf{a}_n} P_n(H^s, \mathbf{a}_n) E(\mathbf{a}_n), \end{aligned} \quad (4.7)$$

where  $E(\mathbf{a}_n)^{ij} = \hat{\epsilon}_{n-1}^{ij}(\mathbf{a}_n) = \mathbb{E}[\epsilon^{ij} | \mathbf{a}_n]$ , defined in equation 4.5, is a conditional expectation over each possible change-point matrix  $\mathbf{a}_n$ .

Equation 4.6 is easier to interpret when  $N = 2$ . Using equation 4.5, we find

$$\hat{\epsilon}_{n-1}^{21}(\mathbf{a}_{n-1}) = \frac{a_{n-1}^{21} + 1}{2 + a_{n-1}^{21} + a_{n-1}^{11}}, \quad \hat{\epsilon}_{n-1}^{12}(\mathbf{a}_{n-1}) = \frac{a_{n-1}^{12} + 1}{2 + a_{n-1}^{12} + a_{n-1}^{22}},$$

and we can express  $\hat{\epsilon}_{n-1}^{11}(\mathbf{a}_{n-1}) = 1 - \hat{\epsilon}_{n-1}^{21}(\mathbf{a}_{n-1})$  and  $\hat{\epsilon}_{n-1}^{22}(\mathbf{a}_{n-1}) = 1 - \hat{\epsilon}_{n-1}^{12}(\mathbf{a}_{n-1})$ . Expanding the sum in equation 4.6, we have

$$\begin{aligned} P_n(H^1, \mathbf{a}_n) &= \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^1(\xi_n) [\hat{\epsilon}_{n-1}^{11}(\mathbf{a}_n - \delta^{11}) P_{n-1}(H^1, \mathbf{a}_n - \delta^{11}) \\ &\quad + \hat{\epsilon}_{n-1}^{12}(\mathbf{a}_n - \delta^{12}) P_{n-1}(H^2, \mathbf{a}_n - \delta^{12})], \end{aligned} \quad (4.8a)$$

$$\begin{aligned} P_n(H^2, \mathbf{a}_n) &= \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f^2(\xi_n) [\hat{\epsilon}_{n-1}^{22}(\mathbf{a}_n - \delta^{22}) P_{n-1}(H^2, \mathbf{a}_n - \delta^{22}) \\ &\quad + \hat{\epsilon}_{n-1}^{21}(\mathbf{a}_n - \delta^{21}) P_{n-1}(H^1, \mathbf{a}_n - \delta^{21})]. \end{aligned} \quad (4.8b)$$

The boundary and initial conditions will be given as above, and the mean inferred transition matrix is given by equation 4.7. Importantly, the inference process described by equations 4.8a and 4.8b allows for both asymmetric change-point matrices,  $\mathbf{a}_n$ , and inferred transition rate matrices  $E(\mathbf{a}_n)$ , unlike the process in equation 3.14. However, the variance of the posteriors over the rates will decrease more slowly, as fewer transitions out of each particular state will be observed.

This algorithm can be used to infer unequal transition rates as shown in Figure 4. Figures 4C through 4E show that the mode of the joint posterior distribution,  $P_n(\epsilon^{21}, \epsilon^{12})$ , approaches the correct rates, while its variance decreases. As in section 3.1, we conjecture that this joint density does not converge to a point mass at the true rate values unless the SNR is infinite.

## 5 Continuum Limits and Stochastic Differential Equation Models \_\_\_\_\_

We next derive continuum limits of the discrete probability update equations for the symmetric case discussed in section 3. We assume that observers make measurements rapidly, so we can derive a stochastic differential equation (SDE) that models the update of an ideal observer's belief (Gold & Shadlen, 2007). SDEs are generally easier to analyze than their discrete counterparts (Gardiner, 2004). For example, response times can be studied by examining mean first passage times of log-likelihood ratios (Bogacz et al., 2006), or log likelihoods (McMillen & Holmes, 2006), which is much easier done in the continuum limit (Redner, 2001). For simplicity, we begin with an analysis of the two-state process and then extend our results

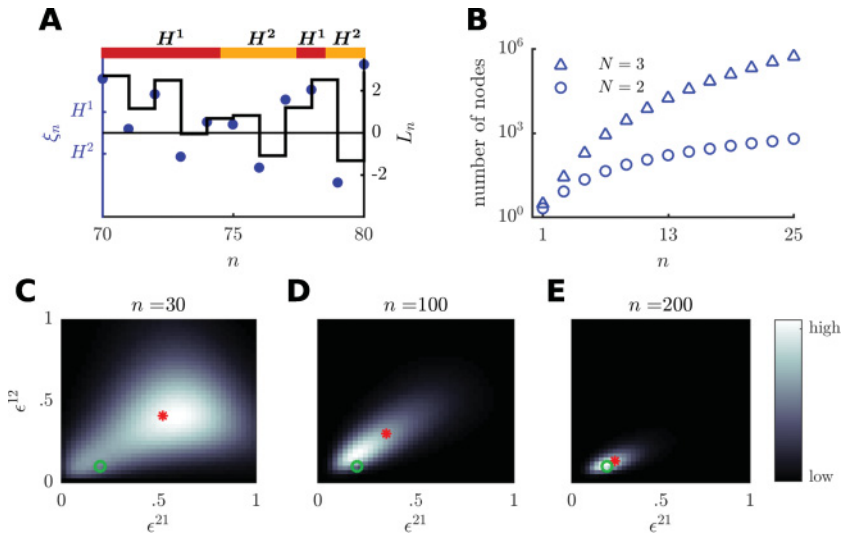

Figure 4: Evidence accumulation and change rates inference in a two-state asymmetric system. (A) Sample path (color bar, top) of the environment between times  $t_{70}$  and  $t_{80}$  (same simulation as in panels C–E) with corresponding observations (blue dots) and log-posterior odds ratio (black step function). Here and in panels C–E,  $(\epsilon^{21}, \epsilon^{12}) = (0.2, 0.1)$ ,  $\text{SNR} = 1.4$ . (B) The number of allowable change-point matrices as a function of observation number,  $n$ , for  $N = 2$  (blue circles) and  $N = 3$  (blue triangles). (C–E) Color plots (gray scale) of the joint density,  $P_n(\epsilon^{21}, \epsilon^{12})$ , with mean value (red star) approaching the true transition rates (green circle).

to the multistate case. The full inference model, Figure 5A, in the two-state case can be reduced using moment closure to truncate the resulting infinite system of SDEs to an approximate finite system (see Figure 5B). This both saves computation time and suggests a potential mechanism for learning the rate  $\epsilon$  of environmental change. We map this approximation to a neural population model in section 6 (see Figure 5C). This model consists of populations that track the environmental state and synaptic weights that learn the transition rate  $\epsilon$ .

## 5.1 Derivation of the Continuum Limit.

**5.1.1 Two-State Symmetric Process.** We first assume that the state of the environment,  $\{H_t\}$ , is a homogeneous continuous-time Markov chain with state-space  $\{H^+, H^-\}$ . The probability of transitions between the two states is symmetric and given by  $P(H_{t+\Delta t} = H^\pm | H_t = H^\mp) = \epsilon \Delta t + o(\Delta t)$ , where  $0 \leq \epsilon < \infty$ . The number of change points,  $a_t$ , up to time  $t$  is a Poisson

Figure 5: Schematic showing the reduction of the full inference model, equation 5.7, for a two-state ( $H^\pm$ ) symmetric environment ( $\epsilon = \epsilon^\pm$ ) carried out in sections 5 and 6. (A) Observations  $\xi_t$  arrive continuously in time and are used to update the probabilities  $P_t^\pm(a)$  that the environment is in state  $H^\pm$  after  $a$  change points. (B) Red and pink arrows from panels A to B represent, respectively, the summation and averaging of  $P_t^\pm(a)$  over  $a$  to obtain equation 5.1b for the zeroth  $\bar{P}_t^\pm$  and first  $\bar{A}_t^\pm$  moments in section 5.2. Arrows from  $P_t^-(a)$  have been omitted for clarity. (C) Moment equations are converted to a neural population model, equation 6.7, by assigning the probabilities to population variables,  $\bar{P}_t^\pm \mapsto u_i^\pm$ , and the ratio of first and zeroth moments to synaptic weights,  $\bar{A}_t^\pm/\bar{P}_t^\pm \mapsto w_i^\pm$ . Orange arrows from panel B demonstrate this mapping. The transition rate  $\epsilon$  is learned by changes in the weights  $w_i^\pm$ . If the observer assumes or knows the rate  $\epsilon$  ahead of time, the weights remain fixed.

process with rate  $\epsilon$ . An observer infers the present state from a sequence of observations,  $\xi_{1:n}$ , made at equally spaced times,<sup>2</sup>  $t_{1:n}$ , with  $\Delta t = t_j - t_{j-1}$ . Each observation,  $\xi_n$ , has probability  $f_{\Delta t}^\pm(\xi_n) := \Pr(\xi_n|H^\pm)$  (see Veliz-Cuba et al., 2016, for more details). We again use the notation  $P_n(H^\pm, a) = P(H_{t_n} = H^\pm, a_t = a|\xi_{1:n})$  where  $t_n$  is the time of the  $n$ th observation.

As in the previous sections, an estimate of the rate parameter,  $\epsilon$ , is obtained from the posterior distribution over the change-point count,  $a_t$ , at the time of the  $n$ th observation,  $t_n$ . For simplicity, we assume a gamma prior with parameters  $\alpha$  and  $\beta$  over  $\epsilon$ , so that  $\epsilon \sim \text{Gamma}(\alpha, \beta)$ . By assumption, the change-point count follows a Poisson distribution with parameter  $\epsilon t_n$ , so that  $P(a_t = a|\epsilon) = (\epsilon t_n)^a e^{-\epsilon t_n}/a!$ . Therefore, once  $a_n$  change points have been observed, we have the posterior distribution  $\epsilon|a_n \sim \text{Gamma}(a_n + \alpha, t_n + \beta)$ , that is,

$$P(\epsilon|a_n) = \frac{(t_n + \beta)^{a_n + \alpha} \epsilon^{a_n + \alpha - 1} e^{-\epsilon(t_n + \beta)}}{\Gamma(a_n + \alpha)}. \tag{5.1}$$

<sup>2</sup>Equal spacing  $\Delta t = t_j - t_{j-1}$  is not necessary for all  $j = 2, \dots, n$ , but it does allow for a more concise derivation of the continuum limit. Irregular spacings would require a more careful selection of the scaling of the log likelihoods  $\ln f^\pm(\xi)$ .

We can substitute equation 5.1 into equation 3.7 describing the probability of transitions between time  $t_{n-1}$  and  $t_n$  to find

$$\begin{aligned}
 &P(H_n, a_n | H_{n-1}, a_{n-1}) \\
 &= \int_0^\infty P(H_n, a_n | \epsilon, H_{n-1}, a_{n-1}) \gamma(\epsilon; a_{n-1} + \alpha, t_{n-1} + \beta) d\epsilon, \tag{5.2}
 \end{aligned}$$

where  $\gamma(\epsilon; \alpha, \beta) = \beta^\alpha \epsilon^{\alpha-1} e^{-\epsilon\beta} / \Gamma(\alpha)$  is the density of the gamma distribution. Using the definition of the transition rate  $\epsilon$ , we can relate it to the first conditional probability in the integral of equation 5.2 via

$$P(H_n, a_n | \epsilon, H_{n-1}, a_{n-1}) = \begin{cases} 1 - \epsilon \Delta t, & \& : H_n = H_{n-1} \ \& \ a_n = a_{n-1}, \\ \epsilon \Delta t, & \& : H_n \neq H_{n-1} \ \& \ a_n = a_{n-1} + 1, \\ 0, & \& : \text{otherwise.} \end{cases} \tag{5.3}$$

We have dropped the  $o(\Delta t)$  terms as we are interested in the limit  $\Delta t \rightarrow 0$ .

Using equation 5.3 and properties of the gamma distribution, we can evaluate the integral in equation 5.2 to obtain

$$P(H_n, a_n | H_{n-1}, a_{n-1}) = \begin{cases} 1 - \Delta t \frac{a_n + \alpha}{t_{n-1} + \beta} & H_n = H_{n-1} \ \& \ a_n = a_{n-1} \\ \Delta t \frac{a_n + \alpha - 1}{t_{n-1} + \beta} & H_n \neq H_{n-1} \ \& \ a_n = a_{n-1} + 1 \\ 0 & \text{otherwise.} \end{cases} \tag{5.4}$$

We can use equation 5.4 in the update equation, equation 3.1, to obtain the probabilities of  $(H_n, a_n)$  given observations  $\xi_{1:n}$ . As before, only terms involving  $a_n - 1$  and  $a_n$  remain in the sum for  $n \geq 1$ . Using the same notational convention as in previous sections, we obtain

$$\begin{aligned}
 P_n(H^\pm, a) &= \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f_{\Delta t}^\pm(\xi_n) \left[ \left( 1 - \Delta t \frac{a + \alpha}{t_{n-1} + \beta} \right) P_{n-1}(H^\pm, a) \right. \\
 &\quad \left. + \Delta t \frac{a + \alpha - 1}{t_{n-1} + \beta} P_{n-1}(H^\mp, a - 1) \right]. \tag{5.5}
 \end{aligned}$$

Note that equation 5.5 is similar to the update equation 3.14 we derived in section 3, with the time index replaced by  $t_{n-1}/\Delta t$  up to the  $\beta$  term. Also, since we have used a gamma instead of a beta distribution as a prior, the

point estimate of the transition rate is slightly different (see equation 3.12). As in the discrete time case, a point estimate of the transition rate is required even before the first change point can be observed. We therefore cannot use an improper prior as the rate point estimate would be undefined.

To take the limit of equation 5.5 as  $\Delta t \rightarrow 0$ , we proceed as in Bogacz et al. (2006) and Veliz-Cuba et al. (2016), working with logarithms of the probabilities. Dividing equation 5.5 by  $P_{n-1}(H^\pm, a)$ , taking logarithms of both sides, and using the notation  $x_{t_n}^\pm(a) := \ln P_n(H^\pm, a)$ , we obtain<sup>3</sup>

$$\Delta x_{t_n}^\pm(a) \propto \ln f_{\Delta t}^\pm(\xi_n) + \ln \left[ 1 - \Delta t \frac{a + \alpha}{t_{n-1} + \beta} + \Delta t \frac{a + \alpha - 1}{t_{n-1} + \beta} e^{x_{t_{n-1}}^\mp (a-1) - x_{t_{n-1}}^\pm(a)} \right].$$

Using the approximation  $\ln(1 + z) \approx z$  for small  $z$  yields

$$\Delta x_{t_n}^\pm(a) \propto \ln f_{\Delta t}^\pm(\xi_n) + \Delta t \left( \frac{a + \alpha - 1}{t_{n-1} + \beta} e^{x_{t_{n-1}}^\mp (a-1) - x_{t_{n-1}}^\pm(a)} - \frac{a + \alpha}{t_{n-1} + \beta} \right).$$

Since the proportionality constant is equal for all  $a$ , we drop it in the SDE for the log-likelihood  $x_t$  (see Veliz-Cuba et al., 2016, for details of the derivation),

$$dx_t^\pm(a) = g_t^\pm dt + dW_t^\pm + \left( \frac{a + \alpha - 1}{t + \beta} e^{x_t^\mp (a-1) - x_t^\pm(a)} - \frac{a + \alpha}{t + \beta} \right) dt, \quad (5.6)$$

where  $g_t^\pm = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} E_\xi [\ln f_{\Delta t}^\pm(\xi) | H_t]$  and  $W^i$  satisfies  $\langle W_t^i W_t^j \rangle = \Sigma_t^{ij} \cdot t$  with  $\Sigma_t^{ij} = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \text{Cov}_\xi [\ln f_{\Delta t}^i(\xi), \ln f_{\Delta t}^j(\xi) | H_t]$  for  $i, j \in \{+, -\}$ .

Note that equation 5.6 is an infinite set of differential equations, one for each pair  $(H^\pm, a)$ ,  $a \in \mathbb{Z}_{\geq 0}$ . The initial conditions at  $t = 0$  are given by  $x^\pm(a) = \ln P_0(H^\pm, a)$ . To be consistent with the prior over the rate,  $\alpha$ , we can choose a Poisson prior over  $a$  with mean,  $\alpha - P_0(a) := \frac{\alpha^\alpha e^{-\alpha}}{\alpha!}$ . The initial conditions for equation 5.6 are given by  $x^\pm = \ln P_0(H^\pm, a) = \ln [P_0(H^\pm) P_0(a)]$ . Note also that equation 5.6 at the boundary  $a = 0$  is a special case. Since at  $a = 0$  there is no influx of probability from  $a - 1$ , equation 5.6 reduces to

$$dx_t^\pm(0) = g_t^\pm dt + dW_t^\pm + \left( (\alpha - 1) e^{-x_t^\pm(0)} - \alpha \right) \frac{dt}{t + \beta}.$$

---

<sup>3</sup>Note that we drop the  $\ln [P(\xi_{1:n-1})/P(\xi_{1:n})]$  term below since it is common to all evolution equations. For determining the most likely option, only the relative magnitudes of the log likelihoods are important. In numerical simulations, we normalize to account for this discrepancy.

Finally, note that we can obtain evolution equations for the likelihoods,  $P_t^\pm(a) = P(H_t = H^\pm, a)$ , by applying the change of variables  $P_t^\pm(a) = e^{x_t^\pm(a)}$ . Itô's change of coordinates rules (Gardiner, 2004) implies that equation 5.6 is equivalent to

$$dP_t^\pm(a) = P_t^\pm(a) \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW_t^\pm \right] + \left[ \frac{a + \alpha - 1}{t + \beta} P_t^\mp(a - 1) - \frac{a + \alpha}{t + \beta} P_t^\pm(a) \right] dt, \tag{5.7}$$

where now initial conditions at  $t = 0$  are simply  $P_0^\pm(a) = P_0(H^\pm, a) = P_0(H^\pm)P_0(a)$ . We will compare the full system, equation 5.7, with an approximation using a moment expansion in section 5.2 (see also Figure 5).

*5.1.2 Two States with Asymmetric Rates.* Next we consider the case where the state of the environment,  $\{H_t\}$ , is still a continuous-time Markov chain with state-space  $\{H^1, H^2\}$ , but the probabilities of transition between the two states are asymmetric:  $P(H_{t+\Delta t} = H^i | H_t = H^j) = \epsilon^{ij} \Delta t + o(\Delta t)$ ,  $i \neq j$ , where  $\epsilon^{12} \neq \epsilon^{21}$ . Thus, we must separately enumerate change points,  $a_t^{i1}$  and  $a_t^{i2}$ , to obtain an estimate of the rates  $\epsilon^{12}$  and  $\epsilon^{21}$ . In addition, we will rescale the enumeration of non-change-points so that  $a_t^{ij} = t^j := a_{\Delta t}^{ij} \Delta t$ , in anticipation of the divergence of  $a_{\Delta t}^{ij}$  as  $\Delta t \rightarrow 0$ . This will mean the total dwell time,  $a_t^{jj}$ , will be continuous, while the change-point count will be discrete. The quantities  $a_t^{ij}$  are then placed into a  $2 \times 2$  matrix,  $A_t = (a_t^{ij}) \in \mathbb{R}^{2 \times 2}$ , where  $a_t^{ij} \in \mathbb{Z}_{\geq 0}$  for  $i \neq j$  and  $a_t^{jj} \in \mathbb{R}_{\geq 0}$ . Note that if the number of change points,  $a_t^{ij}$ , and the total dwell time in a state,  $a_t^{jj} = t^j$ , were known, the change rate could be estimated as  $\tilde{\epsilon}_t^{ij} = a_t^{ij} / a_t^{jj}$ .

As before, we will estimate the rate parameters,  $\epsilon^{ij}$ , using the posterior probability of the change-point matrix,  $A_t$ . We assume gamma priors on each rate, so that  $\epsilon^{ij} \sim \text{gamma}(\alpha_j, \beta_j)$ . By assumption, the change-point count,  $a_t^{ij}$ , follows a Poisson distribution with parameter  $\epsilon^{ij} a_t^{jj}$ , so that  $P(a_t^{ij} = a | \epsilon^{ij} a_t^{jj}) = (\epsilon^{ij} a_t^{jj})^a e^{-\epsilon^{ij} a_t^{jj}} / a!$ . Therefore, once  $a_t^{ij}$  change points have been observed along with the dwell time  $a_t^{jj}$ , we have the posterior distribution  $\epsilon^{ij} | (a_t^{ij}, a_t^{jj}) \sim \text{Gamma}(a_t^{ij} + \alpha_j, a_t^{jj} + \beta_j)$ , so

$$P(\epsilon^{ij} | a_t^{ij}, a_t^{jj}) = \frac{(a_t^{jj} + \beta_j)^{a_t^{ij} + \alpha_j} (\epsilon^{ij})^{a_t^{ij} + \alpha_j - 1} e^{-\epsilon^{ij} (a_t^{jj} + \beta_j)}}{\Gamma(a_t^{ij} + \alpha_j)}. \tag{5.8}$$

We now derive the continuum limit of equation 4.8. One key step of the derivation is the application of a change of variables to the change-point

matrix  $a$ , where we replace the non-change-point counts with dwell times  $t^j$ , defined as  $a_t^{ij} = t^j := a_{\Delta t}^{ij} \Delta t$  for  $\Delta t = t_n - t_{n-1}$ . This is necessary due to the divergence of  $a_{\Delta t}^{ii}$  as  $\Delta t \rightarrow 0$ . In the limit  $\Delta t \rightarrow 0$ , the modified change-point matrix becomes

$$A_t = \begin{pmatrix} t^1 & a^{21} \\ a^{12} & t^2 \end{pmatrix},$$

where  $a_t^{ij} \in \mathbb{Z}^*$  is the change-point count from  $H^j \mapsto H^i$ , while  $t^i \in \mathbb{R}_{\geq 0}$  is the dwell time in state  $H^i$ . Thus, taking logarithms, linearizing, and taking the limit  $\Delta t \rightarrow 0$ , we obtain the following system of stochastic partial differential equations (SPDEs) for the log likelihoods,  $x_t^j(A) = \ln P_n(H^\pm, A)$ :

$$\begin{aligned} dx_t^1(A_t) = & g_t^1 dt + dW_t^1 \\ & + \left( \frac{a_t^{12} + \alpha_2 - 1}{t^2 + \beta_2} e^{x_t^2(A_t) - \delta^{12}} - x_t^1(A_t) - \frac{a_t^{21} + \alpha_1}{t^1 + \beta_1} - \frac{\partial x_t^1}{\partial t^1} \right) dt, \end{aligned} \quad (5.9a)$$

$$\begin{aligned} dx_t^2(A_t) = & g_t^2 dt + dW_t^2 \\ & + \left( \frac{a_t^{21} + \alpha_1 - 1}{t^1 + \beta_1} e^{x_t^1(A_t) - \delta^{21}} - x_t^2(A_t) - \frac{a_t^{12} + \alpha_2}{t^2 + \beta_2} - \frac{\partial x_t^2}{\partial t^2} \right) dt, \end{aligned} \quad (5.9b)$$

where the drift,  $g_t^i$ , and noise,  $W_t^i$ , are defined as before (for details, see section A.3). Note that the flux terms,  $\frac{\partial x_t^i}{\partial t^i}$ , account for the flow of probability to longer dwell times  $t^i$ . For example, the SPDE for  $x_t^1$  has a flux term for the linear increase of the dwell time  $t^1$  since this represents the environment remaining in state  $H^1$ . These flux terms simply propagate the probability densities  $e^{x_t^i(A)} = P_t(H^i, A_t)$  over the space  $(t^1, t^2)$ , causing no net change in the probability of residing in either state  $H^i$ :  $P_t^i = \int_0^\infty \int_0^\infty e^{x_t^i(A_t)} dt^1 dt^2$ .

Equation 5.9 generalizes equation 4.8 as an infinite set of SPDEs, indexed by the discrete variables  $(H^j, a_t^{12}, a_t^{21})$  where  $a_t^{12}, a_t^{21} \in \mathbb{Z}_{\geq 0}$ . Each SPDE is over the space  $(t^1, t^2)$ , and it is always true that  $t^1 + t^2 = t$ . Initial conditions at  $t = 0$  are given by  $x^j(A_t) = \ln [P_0(H^j) \cdot P_0(A_t)]$ . For consistency with the prior on the rates,  $\epsilon^{ij}$ , we choose a Poisson prior over the change-point counts  $a^{ij}$ ,  $i \neq j$  and a Dirac delta distribution prior over the dwell times  $t^i$ ,

$$P_0(A) = \frac{\alpha_1^{a^{21}} e^{-\alpha_1}}{a^{21}!} \frac{\alpha_2^{a^{12}} e^{-\alpha_2}}{a^{12}!} \delta(t^1 - \beta_1) \delta(t^2 - \beta_2). \quad (5.10)$$

As before, equation 5.9 at the boundaries  $a_t^{12} = 0$  and  $a_t^{21} = 0$  is a special case, since there will be no influx of probability from  $a_t^{12} - 1$  or  $a_t^{21} - 1$ .

As in the symmetric case, we can convert equation 5.9 to equations describing the evolution of the likelihoods  $P_t^i(A_t) = P(H_t = H^i, A_t)$ . Applying

the change of variables  $P_t^i(A_t) = e^{x_t^i(A_t)}$ , we find

$$\begin{aligned} dP_t^1(A_t) = & P_t^1(A_t) \left[ \left( g_t^1 + \frac{1}{2} \right) dt + dW_t^1 \right] \\ & + \left[ \frac{a_t^{12} + \alpha_2 - 1}{t^2 + \beta_2} P_t^2(A_t - \delta^{12}) - \frac{a_t^{21} + \alpha_1}{t^1 + \beta_1} P_t^1(A_t) - \frac{\partial P_t^1(A_t)}{\partial t^1} \right] dt, \end{aligned} \tag{5.11a}$$

$$\begin{aligned} dP_t^2(A_t) = & P_t^2(A_t) \left[ \left( g_t^2 + \frac{1}{2} \right) dt + dW_t^2 \right] \\ & + \left[ \frac{a_t^{21} + \alpha_1 - 1}{t^1 + \beta_1} P_t^1(A_t - \delta^{21}) - \frac{a_t^{12} + \alpha_2}{t^2 + \beta_2} P_t^2(A_t) - \frac{\partial P_t^2(A_t)}{\partial t^2} \right] dt, \end{aligned} \tag{5.11b}$$

where now initial conditions at  $t = 0$  are  $P_0^i(A_t) = P_0(H^i)P_0(A_t)$ .

*5.1.3 Multiple States with Symmetric Rates.* The continuum limit in the case of  $N$  states,  $\{H^1, \dots, H^N\}$ , with symmetric transition rates can be derived as with  $N = 2$  (see section A.4 for details). Again, denote the transition probabilities by  $P(H_{t+\Delta t} = H^i | H_t = H^j) = \epsilon^{ij} \Delta t + o(\Delta t)$  and the rate of switching from one to any other state by  $\epsilon = (N - 1)\epsilon^{ij}$ .

Assuming again a gamma prior on the transition rate,  $\epsilon \sim \text{Gamma}(\alpha, \beta)$ , and introducing  $x_t^i(a) := \ln P_n(H^i, a)$ , we obtain the SDE

$$dx_t^i(a) = g_t^i dt + dW_t^i + \left( \frac{a + \alpha - 1}{(N - 1)(t + \beta)} \sum_{j \neq i} e^{x_t^j(a-1) - x_t^i(a)} - \frac{a + \alpha}{t + \beta} \right) dt, \tag{5.12}$$

where  $g_t^i = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} E_\xi [\ln f_{\Delta t}^i(\xi) | H_t]$  and  $W^i$  satisfies  $\langle W^i W^j \rangle = \Sigma_t^{ij} \cdot t$  with  $\Sigma_t^{ij} = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \text{Cov}_\xi [\ln f_{\Delta t}^i(\xi), \ln f_{\Delta t}^j(\xi) | H_t]$ .

Equation 5.12 is again an infinite set of stochastic differential equations, one for each pair  $(H^i, a)$ ,  $i \in 1, \dots, N$ ,  $a \in \mathbb{Z}_{\geq 0}$ . We have some freedom in choosing initial conditions at  $t = 0$ . For example, since  $x^i(a) = \ln P_0(H^i, a)$ , we can use the Poisson distribution discussed in the case of two states.

The posterior over the transition rate,  $\epsilon$ , is

$$P_n(\epsilon) = \sum_{s=1}^N \sum_{a_n=0}^\infty P(\epsilon | a_n) P_n(H^s, a_n),$$

where  $P(\epsilon|a_n)$  is the gamma distribution given by equation 4.9. Similar to equation 3.17, the expected rate is

$$\begin{aligned} \bar{\epsilon} &:= \int_0^\infty \epsilon P_n(\epsilon) d\epsilon = \sum_{s=1}^N \sum_{a_n=0}^\infty \int_0^\infty \epsilon P(\epsilon|a_n) P_n(H^s, a_n) d\epsilon \\ &= \sum_{s=1}^N \sum_{a_n=0}^\infty \frac{a_n + \alpha}{t_n + \beta} P_n(H^s, a_n). \end{aligned}$$

An equivalent argument can be used to obtain the posterior over the rates in the asymmetric case with  $N$  states.

**5.2 Moment Hierarchy for the Two-State Process.** In the previous section, we approximated the evolution of the joint probabilities of environmental states and change-point counts. The result, in the symmetric case, was an infinite set of SDEs, one for each combination of state and change-point values  $(H^i, a)$ . However, an observer is mainly concerned with the current state of the environment. The change-point count is important for this inference but may not be of direct interest itself. We next derive simpler, approximate models that do not track the entire joint distribution over all change-point counts, only essential aspects of this distribution. We do so by deriving a hierarchy of iterative equations for the moments of the distribution of change-point counts,  $a \in \mathbb{Z}_{\geq 0}$ , focusing specifically on the two-state symmetric case.

Our goal in deriving moment equations is to have a low-dimensional, and reasonably tractable, system of SDEs. Similar to previous studies of sequential decision-making algorithms (Bogacz et al., 2006), such low-dimensional systems can be used to inform neurophysiologically relevant population rate models of the evidence accumulation process. To begin, we consider the infinite system of SDEs given in the two-state symmetric case, equation 5.7. Our reduction then proceeds by computing the SDEs associated with the lower order (zeroth, first, and second) moments over the change-point count  $a$ :

$$\bar{P}_t^\pm = \sum_{a \in \mathbb{Z}_{\geq 0}} P_t^\pm(a), \quad \bar{a}_t^\pm = \sum_{a \in \mathbb{Z}_{\geq 0}} (a + \alpha) P_t^\pm(a), \quad \bar{b}_t^\pm = \sum_{a \in \mathbb{Z}_{\geq 0}} (a + \alpha)^2 P_t^\pm(a). \tag{5.13}$$

We denote the moments using bars ( $\bar{b}_t^\pm$ ). Below, when we discuss cumulants, we will represent them using hats ( $\hat{b}_t^\pm$ ). Note that the “zeroth” moments are the marginal probabilities of  $H^+$  and  $H^-$ .

We begin by summing equation 5.7 over all  $a \in \mathbb{Z}_{\geq 0}$  and applying equation 5.13 to find this generates an SDE for the evolution of the moments  $\bar{P}_t^\pm$  given

$$d\bar{P}_t^\pm = \bar{P}_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW_t^\pm \right] + \frac{1}{t + \beta} [\bar{a}_t^\mp - \bar{a}_t^\pm] dt, \tag{5.14}$$

where we have used the fact that

$$\overline{(a - 1)}_t^\pm = \sum_{a=1}^\infty (a + \alpha - 1) P_t^\pm(a - 1) = \sum_{a=0}^\infty (a + \alpha) P_t^\pm(a) = \bar{a}_t^\pm.$$

The SDE given by equation 5.14 for the zeroth moment,  $\bar{P}_t^\pm$ , depends on the first moment,  $\bar{a}_t^\pm$ . We can determine values for the first moment by either obtaining the next SDE in the moment hierarchy or assuming a reasonable functional form for  $\bar{a}_t^\pm$ . For instance, if the transition rate  $\epsilon$  is known, we can assume  $\bar{a}_t^\pm := (t + \beta)\epsilon\bar{P}_t^\pm + \mathcal{O}(1)$ , so that  $\bar{a}_t^+ + \bar{a}_t^-$  is approximately the mean of the counting process with rate  $\epsilon$ . In this case, the continuum limit  $t \rightarrow \infty$  of equation 5.14 becomes

$$d\bar{P}_t^\pm = \bar{P}_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW_t^\pm \right] + \epsilon \cdot [\bar{P}_t^\mp - \bar{P}_t^\pm] dt.$$

As expected, this is the two-state version of equation 2.2, with known rate,  $\epsilon$ . However, if the observer has no prior knowledge of the rate,  $\epsilon$ , then  $\bar{a}_t^\pm$  should evolve toward  $(t + \beta)\epsilon\bar{P}_t^\pm$  at a rate that depends on the noisiness of observations.

To obtain an equation for  $\bar{a}_t^\pm$  we multiply equation 5.7 by  $(a + \alpha)$  and sum to yield

$$d\bar{a}_t^\pm = \bar{a}_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW_t^\pm \right] + \frac{1}{t + \beta} [\bar{a}_t^\mp + \bar{b}_t^\mp - \bar{b}_t^\pm] dt. \tag{5.15}$$

This equation relates the first and second moments,  $\bar{a}_t^\pm$  and  $\bar{b}_t^\pm$ . Again, we require an expression for the next moment,  $\bar{b}_t^\pm$ , to close the system of equations 5.14 and 5.15. We could obtain an equation for  $\bar{b}_t^\pm$  by multiplying equation 3.7 by  $(a + \alpha)^2$  and summing. However, as is typical with moment hierarchies, we would not be able to close the system as equations for subsequent moments will depend on successively higher moments (Socha, 2007; Kuehn, 2016). To close the equations for  $\bar{P}_t^\pm, \bar{a}_t^\pm, \dots$  we can truncate. One possibility is cumulant neglect (Whittle, 1957; Socha, 2007), which

assumes all cumulants above a given order grow more slowly than the moment itself and can thus be ignored. This allows one to express the highest-order moment as a function of the lower-order moments, since a moment is an algebraic function of its associated cumulant and lower moments. For instance, neglecting the second cumulant  $\hat{b}_t^\pm \approx 0$  allows us to approximate the second moment as  $\bar{b}_t^\pm = \hat{b}_t^\pm + (\bar{a}_t^\pm)^2 \approx (\bar{a}_t^\pm)^2$ .<sup>4</sup>

Applying cumulant neglect to the second moment,  $\bar{b}_t^\pm$ , in equations 5.14 and 5.15, using the change of variables,  $\bar{A}_t^\pm = \bar{a}_t^\pm / (t + \beta)$ , and the fact that  $d\bar{A}_t^\pm = [(t + \beta)d\bar{a}_t^\pm - \bar{a}_t^\pm dt] / (t + \beta)^2$ , we obtain a closed system of equations for the zeroth and first moments,

$$d\bar{P}_t^\pm = \bar{P}_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW^\pm \right] + [\bar{A}_t^\mp - \bar{A}_t^\pm] dt, \tag{5.16a}$$

$$d\bar{A}_t^\pm = \bar{A}_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW^\pm \right] + (\bar{A}_t^\mp - \bar{A}_t^\pm) \left( \frac{1}{t + \beta} + \bar{A}_t^\mp + \bar{A}_t^\pm \right) dt. \tag{5.16b}$$

Here initial conditions are given by  $\bar{P}_0^\pm := P_0(H^\pm)$  and  $\bar{A}_0^\pm = \alpha P_0(H^\pm) / \beta$ . We show in section A.5 that equation 5.16 is also consistent with equation 2.2, which holds in the case of two states and known rate  $\epsilon$ . Trajectories of equation 5.16 are shown in Figure 6. Note that both  $\bar{P}_t^\pm$  and  $\bar{A}_t^\pm$  tend to increase when  $g_t^\pm$  is the maximal drift rate, that is, when  $H^\pm$  is the true environmental state. Thus, we expect that when  $\bar{P}^\pm$  is high (close to unity),  $\bar{A}_t^\pm$  will tend to be larger than  $\bar{A}_t^\mp$ .

Immediately after a change point (where the maximal drift rate  $g_t^\pm$  changes), there is an additional contribution to the increase of  $\bar{A}_t^\pm$  due to the  $(\bar{A}_t^\mp - \bar{A}_t^\pm)$  term. It is this brief burst of additional input to the subsequently dominant variable that generates the counting process, enumerating the change points. For instance, when a  $H^+ \mapsto H^-$  switch occurs, an increase in  $\bar{A}_t^-$  will temporarily be driven by both the drift term,  $g_t^-$ , and the nonlinear term involving  $(\bar{A}_t^+ - \bar{A}_t^-)$ . The burst of input generated by the nonlinear term in equation 5.16b has an amplitude that decays nonautonomously with time. In fact, it can be shown that when the signal-to-noise ratio of the system is quite high, the variables  $\bar{A}_t^\pm \approx (m + \alpha) / (t + \beta)$ , which is effectively the true change-point count  $m$  divided by elapsed time as modified by the prior.

We can also obtain a point estimate of the transition rate of the environment, which we define as  $\tilde{\epsilon}_t := \bar{A}_t^+ + \bar{A}_t^-$ , since the following relations

---

<sup>4</sup>We have used a hat to distinguish cumulants ( $\hat{b}_t^\pm$ ), whereas bars still denote moments ( $\bar{b}_t^\pm$ ).

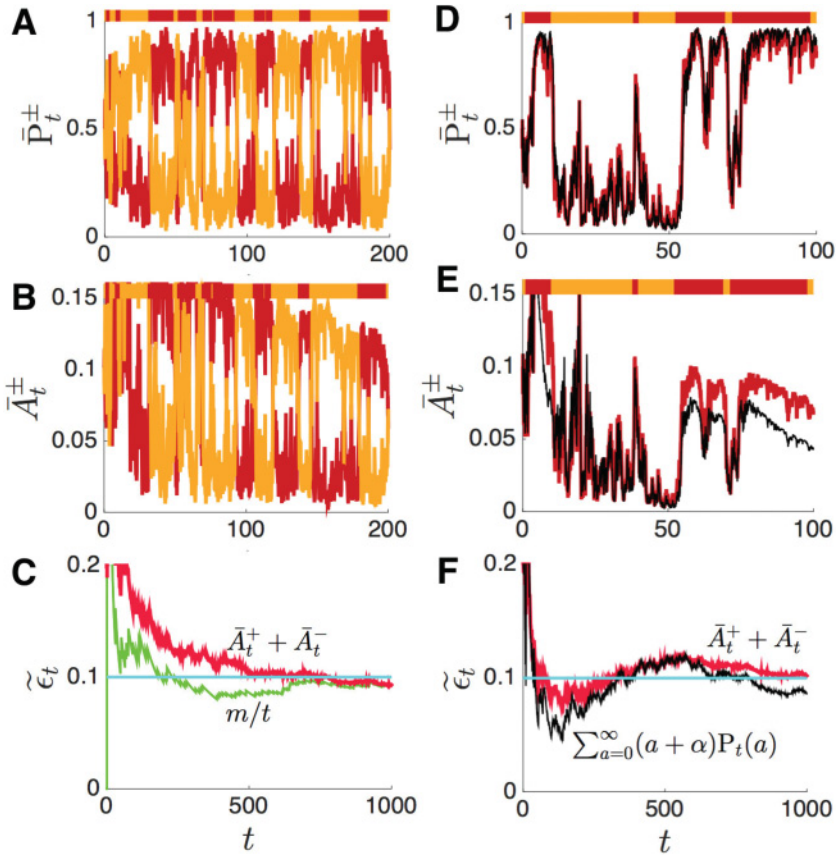

Figure 6: The dynamics of the first two moments as approximated by equation 5.16. (A) The probabilities  $\bar{P}_t^\pm$  track the present state of the environment (bar above), switching with rate  $\epsilon = 0.1$ , and approach the stationary densities around the equilibria determined by the dichotomous drift terms  $g_t^\pm$ . (B) The first moments,  $\bar{A}_t^\pm$ , also switch with the environmental state and alternate between the neighborhoods of two points. (C) The sum  $\bar{\epsilon}_t := \bar{A}_t^+ + \bar{A}_t^-$  provides a running point estimate of the environmental transition rate,  $\epsilon$ , as shown in equation 5.17. The estimate is determined by the actual change points and noisily tracks  $m/t$ , where  $m$  is the actual number of change points. (D–F) Same as panels A–C, but the moment simulations are compared with numerical simulations of the full system of SDEs given by equation 5.7. (D) The thick red line is  $\bar{P}_t^\pm$  from equation 5.16, and the thin black line is  $\sum_{a=0}^\infty P_t^+(a)$  using equation 5.7. (E) The thick red line is  $\bar{A}_t^\pm$  from equation 5.16, and the thin black line is  $\sum_{a=0}^\infty (a + \alpha) P_t^+(a)$  using equation 5.7. (F) Estimates of  $\bar{\epsilon}_t$  using equation 5.16 and equation 5.7. Details about the simulation method, initial conditions, and parameters are provided in section A.9.

hold:

$$\begin{aligned}\bar{A}_t^+ + \bar{A}_t^- &= \frac{1}{t + \beta} \sum_{a \in \mathbb{Z}_{\geq 0}} (a + \alpha) [\text{P}(H^+, a | \xi_t) + \text{P}(H^-, a | \xi_t)] \\ &= \sum_{a \in \mathbb{Z}_{\geq 0}} \frac{(a + \alpha)}{t + \beta} \text{P}(a | \xi_t) = \int_0^\infty \epsilon \sum_{a \in \mathbb{Z}_{\geq 0}} \text{P}(\epsilon | a) \text{P}(a | \xi_t) d\epsilon.\end{aligned}\quad (5.17)$$

This estimate is an average over the distribution of possible change-point counts,  $a$ , given the observations,  $\xi_t$ . Here  $\text{P}(\epsilon | a)$  is a gamma distribution with parameters  $\alpha$  and  $\beta$ . In Figure 6C we compare this approximation,  $\tilde{\epsilon}_t$ , with the true change rate  $\epsilon$  and the running estimate  $m/t$ , obtained from the actual number of change points,  $m$ .

In Figures 6D and 6E, these approximations are compared to equation 5.7, the full SDE giving the distribution over all change-point counts,  $a$ . Notice that the first moments  $\bar{A}_t^\pm$  are overestimates of the true average,  $\sum_{a=0}^\infty (a + \alpha) \text{P}_t^\pm(a) / (t + \beta)$ , obtained from equation 5.7. We expect this is due to the fact that the moment equations, equation 5.16, tend to overcount the number of change points. Fluctuations lead to an increase in the number of events whereby  $\bar{A}_t^+$  and  $\bar{A}_t^-$  exchange dominance ( $\bar{A}_t^+ = \bar{A}_t^-$ ), which will lead to a burst of input to one of the variables  $\bar{A}_t^\pm$ . As a consequence, the transition rate tends to be overestimated by equation 5.16 compared to equation 5.7.

In sum, while the inference approximation given by equation 5.16 does not provide an estimate of the variance, it does provide insight into the computations needed to estimate the change-point count and transition probability. Transitions increment the running estimate of the change-point count, and this increment decays over time, inversely with the total observation time  $t$ . Similar equations for the moments can be obtained in the case of asymmetric transition rates, or more than two choices using equations 5.11 and 5.12, respectively, although we omit their derivations here.

## 6 Learning Transition Rate in Neural Populations with Plasticity \_\_\_\_\_

Models of decision making often consist of mutually inhibitory neural populations with finely tuned synaptic weights (Machens, Romo, & Brody, 2005; McMillen & Holmes, 2006; Wong, Huk, Shadlen, & Wang, 2007). For instance, many models of evidence integration in two alternative choice tasks assume that synaptic connectivity is tuned so that the full system exhibits line attractor dynamics in the absence of inputs. Such networks integrate inputs perfectly and maintain this integrated information in memory after the inputs are removed. However, in changing environments, optimal evidence integration should be leaky, since older information becomes irrelevant for the present decision (Deneve, 2008; Glaze et al., 2015).

We previously showed that optimal integration in changing environments can be implemented by mutually excitatory neural populations (Veliz-Cuba et al., 2016). Instead of a line attractor, the resulting dynamical systems contain globally attracting fixed points. Such leaky integrators maintain a limited memory of their inputs on a timescale determined by the frequency of environmental changes. However, in this previous work, we assumed that the rates of the environmental changes were known to the observer. Here, we show that when these rates are not known a priori, a plastic neuronal network is capable of learning and implicitly representing them through coupling strengths between neural populations.

**6.1 Symmetric Environment.** We begin with equation 5.16, the leading-order equations for the likelihood  $\bar{P}_t^\pm$  and change rate variables  $\bar{A}_t^\pm$  derived in section 5.2. We interpret the likelihoods as neural population activity variables  $u_t^\pm := \bar{P}_t^\pm$ , reflecting a common modeling assumption that two populations receive separate streams of input associated with evidence for either choice (Bogacz et al., 2006). Next, we define a new variable  $w_t^\pm := \bar{A}_t^\pm / \bar{P}_t^\pm$ , which represents the synaptic weight between these neural populations (see Figure 5C). In particular,  $w_t^\pm$  represents the strength of coupling from  $u_t^\pm$  to  $u_t^\mp$ , as well as the local inhibitory coupling within  $u_t^\pm$ . Applying this change of variables to equation 5.16, we derive a set of equations for the population activities,  $u_t^\pm$ , and their associated synaptic weights,  $w_t^\pm$ :

$$du_t^\pm = u_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW_t^\pm \right] + [w_t^\mp u_t^\mp - w_t^\pm u_t^\pm] dt \quad (6.1a)$$

$$dw_t^\pm = - \left[ w_t^\pm + w_t^\mp - \frac{w_t^\mp}{u_t^\pm} \right] \left[ \frac{1}{t + \beta} + u_t^\mp (w_t^\mp - w_t^\pm) \right] dt. \quad (6.1b)$$

This is a neural population model with a rate-correlation-based plasticity rule (Miller, 1994; Pfister & Gerstner, 2006). Each neural population  $u_t^\pm$  affects its neighboring population via mutual excitation as in Veliz-Cuba et al. (2016). Note that each population in equation 6.1 is also locally affected by self-inhibition, whose weight evolves according to the same dynamics as the excitatory weights between populations. We expect that such dynamics could arise as the quasi-static approximation of a network with separate excitatory and inhibitory populations, but we save such analyses for future work. We can interpret the nonautonomous term,  $1/(t + \beta)$ , as modeling the dynamics of a chemical agent involved in the plasticity process whose availability decays over time. Simple chemical degradation kinetics for a concentration  $C_t$  yield such a function when

$$dC_t = -C_t^2 dt, \quad C_0 = 1/\beta \quad \Rightarrow \quad C_t = \frac{1}{t + \beta}. \quad (6.2)$$

We briefly analyze the model, equation 6.1, by considering the limit of no observation noise. That is, we assume  $g_t^\pm \rightarrow \pm\infty$  when  $H_t = H^+$  and  $\Sigma^{++} \rightarrow 0$ , where  $\langle W_t^+ W_t^+ \rangle = \Sigma_t^{++} \cdot t$ , and analogous relations hold when  $H_t = H^-$ . As a result, when  $H_t = H^+$ , then  $u_t^+ \rightarrow 1$  and  $u_t^- \rightarrow 0$ , which we demonstrate in section A.6. Plugging the expressions  $u_t^+ = 1$  and  $u_t^- = 0$  into equation 6.1b for  $w_t^+$ , we find

$$dw_t^+ = - \left[ \frac{1}{t + \beta} \right] w_t^+ dt. \quad (6.3)$$

Next, we write equation 6.1b for  $w_t^-$  in the form

$$u_t^- dw_t^- = - [u_t^- w_t^- + u_t^- w_t^+ - w_t^+] \left[ \frac{1}{t + \beta} + u_t^+ (w_t^+ - w_t^-) \right] dt,$$

so by plugging in  $u_t^+ = 1$  and  $u_t^- = 0$ , we find  $0 = w_t^+ [\frac{1}{t+\beta} + w_t^+ - w_t^-]$ , which, when  $w_t^+ \neq 0$ , simplifies to

$$w_t^- = w_t^+ + \frac{1}{t + \beta}. \quad (6.4)$$

An analogous pair of equations holds when  $H_t = H^-$  and thus  $u_t^- \rightarrow 1$  and  $u_t^+ \rightarrow 0$ . Solving equations 6.3 and 6.4 and their  $H_t = H^-$  counterparts iteratively, we find that in the limit of no observation noise (e.g.,  $g_t^\pm \rightarrow \pm\infty$  when  $H_t = H^\pm$ ),

$$w_t^\pm = \frac{w_0 \beta + m_t}{t + \beta}, \quad w_t^\mp = \frac{w_0 \beta + m_t + 1}{t + \beta}, \quad (6.5)$$

where  $H_t = H^\pm$  and  $w_0 := w^j(0)$  for  $H(0) = H^j$ , so  $w_0$  constitutes the initial estimate of the change rate of the environment. Here,  $m_t$  is the number of change points in the time series  $H_t$  during the time interval  $[0, t]$ . Equation 6.5 can be reexpressed in the form of a rate-based plasticity rule,

$$dw_t^\pm = [\delta(u_t^+ - u_t^-) - w_t^\pm] \cdot C_t dt, \quad (6.6)$$

where  $\delta(u)$  is the Dirac delta distribution, along with equation 6.2 for the concentration decay of the agent  $C_t$ . Note that the nonnegative term  $\delta(u_t^+ - u_t^-)$  in equation 6.6 results in long-term potentiation (LTP) of both synaptic weights,  $w_t^\pm$ , whenever the neural activities,  $u_t^\pm$ , are both high, that is, when their values cross at  $u_t^\pm = 0.5$ . During such changes, the weights  $w_t^\pm$  are incremented. Outside of these transient switching epochs, there is long-term depression (LTD) of the synaptic weights  $w_t^\pm$  modeled by the term  $(-w_t^\pm)$ .

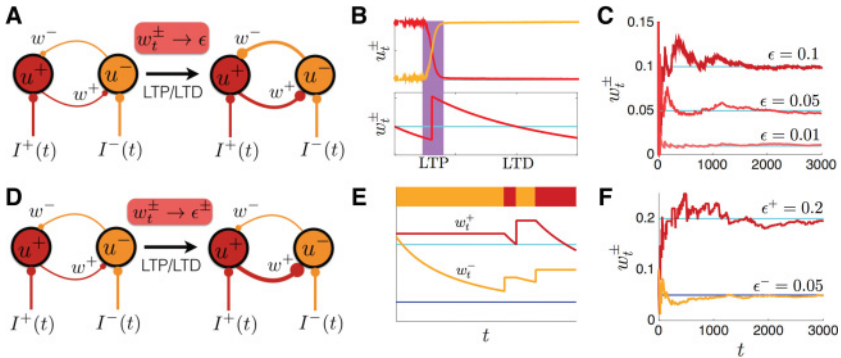

Figure 7: Neural network model with plasticity, inferring the current state  $H_t$  and rates  $\epsilon^\pm$  of environmental change. (A) Schematic showing the synaptic weight  $w^\pm$  from neural population  $u^\pm \mapsto u^\mp$  evolving through long-term potentiation (LTP) and long-term depression (LTD) to match the environment's rate of change,  $\epsilon^\pm := \epsilon$ . (B) When the neural populations exchange dominance, their activity levels  $u^\pm$  are both transiently high. As a result, both synaptic weights,  $w^\pm$ , increase via LTP. When only one population is active, both weights decay via LTD, as described by equation 6.7b. (C) Inference of the rate,  $\epsilon$ , via long-term plasticity of the weights for  $\epsilon = 0.01, 0.05, 0.1$ . Though the signal-to-noise ratio is finite (see section A.9), the weights in the network described by equation 6.7 converge to the actual rate,  $\epsilon$ . (D) Schematic showing the evolution of weights  $w_i^\pm$  when rates are asymmetric,  $\epsilon^+ > \epsilon^-$ , so that  $w_\infty^+ > w_\infty^-$ . The network is described by equation 6.9. (E) Only the weight  $w_i^\pm$  decays through LTD when population  $u_i^\pm$  is active, and only the weight  $w_i^\pm$  is potentiated through LTP when dominance switches from  $u_i^\pm$  to  $u_i^\mp$ , as in equation 6.9. (F) Network weights  $w_i^\pm$  converge to the asymmetric rates,  $\epsilon^\pm$ . See section 7.9 for details about the simulations.

We schematize in Figure 7A and simulate in Figures 7B and 7C the resulting plastic neural population network:

$$du_i^\pm = u_i^\pm [I_t^\pm dt + dW_t^\pm] + [w_i^\mp u_i^\mp - w_i^\pm u_i^\pm] dt \quad (6.7a)$$

$$dw_i^\pm = [\delta(u_i^+ - u_i^-) - w_i^\pm] \cdot C_t dt. \quad (6.7b)$$

The constant  $1/2$  has been absorbed into the population input, so that  $I_t^\pm = g_t^\pm + 1/2$ . It is important to note that equation 6.7 performs optimal inference only in the limit of no observation noise. Perturbing away from this case, we expect the performance to be suboptimal. However, as can be seen in Figure 7C, the correct change rate is approximated reasonably well.

Many previous neural population models of evidence accumulation assume that neural activity represents log probabilities or log likelihoods (Bogacz et al., 2006; McMillen & Holmes, 2006; Veliz-Cuba et al., 2016). In

our model the rate variables,  $u_t^\pm$ , represent the probability that the environment is in state  $H^\pm$ . This particular form of the population model leads dynamical equations that are consistent with an accepted rate-correlation-based plasticity rule (Miller, 1994; Pfister & Gerstner, 2006). Using log probabilities would lead to models that contain exponential functions of the rate (Veliz-Cuba et al., 2016), which are less common. In addition, since probabilities can assume a finite range of values, we required that  $u_t^\pm \in [0, 1]$ . Using log probabilities would require that we use a semi-infinite range,  $(-\infty, 0]$  or that we truncate. Note also that the inputs  $I_t^\pm$  and noise  $dW_t^\pm$  are gain-modulated using the population rates  $u_t^\pm$ . Gain-modulating circuits have been identified in many sensory areas (Salinas & Abbott, 1996), and recent studies suggest evidence-accumulating circuits may also modulate input in a history-dependent way (Wyart, De Gardelle, Scholl, & Summerfield, 2012).

Equation 6.7 thus models evidence accumulation in a symmetrically changing environment when the change rate,  $\epsilon$ , is not known a priori. The model is based on the recursive equation for the joint probability of the environmental state,  $H^\pm$ , and change-point count,  $a$ , derived in section 3.1. We obtained a tractable model by first passing to the continuum limit and then applying a moment closure approximation to reduce the dimension of the resulting equations. Obtaining the low-dimensional approximation in equation 5.16 was crucial to obtaining a neural population model that approximates state inference. We next extend this model to the case of asymmetric rates of change.

**6.2 Asymmetric Environment.** The continuum limit of the inference process in an asymmetric environment, equation 5.11, provides several pieces of information we can use to identify an approximate neural population model. First, under the assumption of large signal-to-noise ratios, the synaptic weights should evolve to reflect the number of detected change-points, rescaled by the amount of time spent in each state

$$w_t^+ = \frac{w_0^+ \beta^+ + m_t^+}{t^+ + \beta^+}, \quad w_t^- = \frac{w_0^- \beta^- + m_t^-}{t^- + \beta^-}, \quad (6.8)$$

where  $w_0^\pm := w^\pm(0)$  are the network's initial estimates of the change rates  $\epsilon^\pm$ ,  $m_t^\pm$  is the true number of change points  $H^\pm \mapsto H^\mp$  during the time interval  $[0, t]$ , and  $t^\pm$  is the total length of time spent in the state  $H^\pm$ .<sup>5</sup> Second, the flux term in equation 5.11 indicates that a memory process is needed to store the estimated time  $t^\pm$  spent in each state  $H^\pm$ . This can be accomplished by

---

<sup>5</sup>We use the notation  $H^\pm$  for the two states here, for convenience and consistency with equation 6.7. Similarly, we use  $\epsilon^\pm$  and  $t^\pm$  rather than the numerical notation of the asymmetric case in section 5.1.

modifying equation 6.2 for the plasticity agent, so that each  $C_t^\pm$  decays only when the neural population of origin,  $u_t^\pm$ , is active. Thus, we obtain the pair of equations

$$dC_t^\pm = -H(u_t^\pm - \theta) [C_t^\pm]^2.$$

Expressing equation 6.8 as a system of equations for the synaptic weights,  $w_t^\pm$ , yields

$$dw_t^\pm = H(u_{t-\tau}^\pm - \theta) [\delta(u_t^+ - u_t^-) - w_t^\pm] \cdot C_t^\pm dt. \quad (6.9)$$

Here the function  $H(u^\pm(t - \tau) - \theta)$  for  $\theta \geq 0.5$ , and  $\tau > 0$  enforces the requirement that the population  $u_t^\pm$  must have a high rate of activity prior to the LTP event. Thus, to learn asymmetric weights, there should be a small delay  $\tau$  accounting for the time it takes for the presynaptic firing rate to trigger the plasticity process (Gütig, Aharonov, Rotter, & Sompolinsky, 2003). We demonstrate the performance of the network whose weights evolve according to equation 6.9 in Figures 7D and 7E. The network with weights evolving according to equation 6.9 can still infer symmetric transition rates  $\epsilon^\pm = \epsilon$ , but it will do so at half the rate of the network, equation 6.7. This is due to the fact that equation 6.9 counts the change points and dwell times of each state  $H^\pm$  separately.

We have thus shown that the recursive update equations for the state probability in a dynamic environment lead to plausible neural network models that approximate the same inference. Previous neural network models of decision making have tended to interpret population rates as a representation of posterior probability (Bogacz et al., 2006; Beck et al., 2008). We have shown that the synaptic weight between populations can represent the change rate of the environment. As a result, standard rate-correlation models of plasticity can be used to implement the change rate inference process.

## 7 Discussion

---

Evidence integration models have a long history in neuroscience (Ratcliff & McKoon, 2008). These normative models conform with behavioral observations across species (Brunton et al., 2013), and have been used to explain the neural activity that underpins decisions (Gold & Shadlen, 2007). However, animals make decisions in an environment that is seldom static (Portugues & Engert, 2009). The relevance of available information, the accessibility, and the payoff of different choices can all fluctuate. It is thus important to extend evidence accumulation models to such cases.

We have shown how ideal observers accumulate evidence to make decisions when there are multiple, discrete choices, and the correct choice

changes in time. We assumed that the rates of transition between environmental states are initially unknown to the observer. An ideal observer must therefore integrate information from measurements to concurrently estimate both the transition rates and the current state of the environment. Importantly, these two inference processes are coupled: knowledge of the rate allows the observer to appropriately discount older information to infer the current state, while knowledge of transitions between states is necessary to infer the rate.

Inference when all transition rates are identical is straightforward to implement in resulting models. An ideal observer only needs to track the probability of the environmental state and the total change-point count regardless of the states between which the change occurred. However, when the transition rates are asymmetric, the resulting models are more complex. In this case, an ideal observer must estimate a matrix of change-point counts, distinguished by the starting and ending states. The number of possible matrices grows polynomially with the number of observations. This computation is difficult to implement, and we do not suggest that animals make inferences about environmental variability in this way. However, understanding the ideal inference process allowed us to identify its most important features. In turn, we derived tractable approximations and plausible neural implementations, whose performance compared well with that of an ideal observer (see Figures 6D–6F). We believe humans and other animals do generally implement approximate strategies when they need to infer such rates (Lange & Dukas, 2009). Ideal observer models allow us to understand what inferences can be made with the available information, which assumptions of the observer are important (e.g., assuming an incorrect transition rate does not always have a large impact on performance), and how such inferences could be approximated in networks of the brain and other biological computers.

In many naturally occurring decisions like foraging, mate selection, and home site choice, animals simply need to identify the best alternative rather than the rate of environmental change (Johnson, Blumstein, Fowler, & Haselton, 2013). Therefore, rapid approximations, or a guess of the environmental change rate may provide better initial performance than learning the rate, which could be slow. Moreover, it appears that when measurements are noisy, rates cannot be learned precisely even in the limit of infinite observations. Thus, learning the rate may improve performance only when noise is too high for single measurements to determine the correct alternative but sufficiently low to make rate inference possible. It is within this range of parameters that we expect to be able to distinguish the performance of our normative model from that of different approximations. We plan to carry out such a systematic comparison of model performance in future work. There is evidence that humans adjust their rate of evidence discounting based on the actual change rate of the environment (Glaze et al., 2015). However, further psychophysical studies are needed to identify whether subjects use heuristic

strategies to learn or something close to the normative models we derived here.

A number of related models have been developed previously (Wilson et al., 2010; Adams & MacKay, 2007). Our model is somewhat different, as a finite number of choices implies that the current environmental state is dependent on the previous state. As a result, we found it was more efficient to implement an update equation that estimated the current environmental state and the change points rather than the time in the current state.

Several of the assumptions we have made in this study could be modified to extend our analysis to more general situations. For instance, we have assumed that the observer's eventual choice does not affect the environment. However, in many natural situations, changes in the environment are a consequence of the observer's actions (Cisek & Pastor-Bernier, 2014). In more realistic situations, it is likely that a sequence of actions leads to an ultimate decision, and each action can influence the information available to the observer. An animal making a foraging decision in a group collects more evidence once it moves toward a particular food patch, but it may also draw other members with it, changing the subsequent availability of food there (Petit, Gautrais, Leca, Theraulaz, & Deneubourg, 2009). Thus, including a sequence of actions and their impact on the available information and the environment would be necessary in a realistic model. Another possibility is that changes to the environment are non-Markovian or involve multiple timescales. Extending our ideal observer models to estimate such change statistics might require derivation of multistep update equations. In such cases, we expect the truncations we have applied in this work would be useful for identifying tractable approximations of the optimal inference process.

Optimal models of evidence accumulation are useful as baselines to compare to performance in psychophysical experiments and starting points for identifying plausible neuronal network implementations. Our core contribution here has been to present a general model of evidence accumulation in a dynamic environment when an observer has no prior knowledge of the rate of change. An unavoidable feature of these models is that the number of variables the observer must track grows as more observations are made, and growth is more rapid in asymmetric environments with multiple environmental states. This motivated our development of continuum approximations and low-dimensional moment equations for the optimal models, which suggest more plausible neural computations. We hope this work will foster future theoretical studies that will extend this framework, as well as experiments that could validate the models here. To fully understand the neural mechanisms of evidence accumulation, we must account for the wide variety of conditions that organisms encounter when making decisions.

**Appendix: Analytical Calculations and Numerical Methods** \_\_\_\_\_

**A.1 Two-State System with Unknown Symmetric Rate.** We show how to derive equation 3.1 from the main text. Bayes’ rule and the law of total probability first yield

$$P_n(H_n, a_n) = \frac{1}{P(\xi_{1:n})} \sum_{H_{n-1}=H^\pm} \sum_{a_{n-1}=0}^{n-2} P(\xi_{1:n}|H_n, H_{n-1}, a_n, a_{n-1}) \times P(H_n, H_{n-1}, a_n, a_{n-1}).$$

Using the conditional independence of observations,

$$P(\xi_{1:n}|H_n, H_{n-1}, a_n, a_{n-1}) = P(\xi_n|H_n)P(\xi_{1:n-1}|H_{n-1}, a_{n-1}),$$

we find that

$$P_n(H_n, a_n) = \frac{1}{P(\xi_{1:n})} \sum_{H_{n-1}=H^\pm} \sum_{a_{n-1}=0}^{n-2} P(\xi_n|H_n)P(\xi_{1:n-1}|H_{n-1}, a_{n-1}) \times P(H_n, H_{n-1}, a_n, a_{n-1}).$$

Furthermore, we can use the definition of conditional probability to write

$$P(H_n, H_{n-1}, a_n, a_{n-1}) = P(H_n, a_n|H_{n-1}, a_{n-1})P(H_{n-1}, a_{n-1}),$$

and Bayes’ rule also implies

$$P(\xi_{1:n-1}|H_{n-1}, a_{n-1})P(H_{n-1}, a_{n-1}) = P_{n-1}(H_{n-1}, a_{n-1})P(\xi_{1:n-1}).$$

Hence, we derive equation 3.1 from the main text,

$$P_n(H_n, a_n) = \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} P(\xi_n|H_n) \sum_{H_{n-1}=H^\pm} \sum_{a_{n-1}=0}^{n-2} P_{n-1}(H_{n-1}, a_{n-1}) \times P(H_n, a_n|H_{n-1}, a_{n-1}).$$

**A.2 Numerical Methods for Free Response Protocol.** The free response protocol is simulated by evolving the update equation 3.14 and subsequently computing the log-likelihood ratio  $L_n := \log(R_n)$  using equation 3.16 at each time step  $n$ . Each point along the curves in Figure 3C corresponds to an average waiting time and average performance corresponding

to a threshold value  $\theta$  over 100,000 simulations. For each value of  $\theta$ , the simulation is terminated when  $|L_n| > \theta$  and the choice is given by the sign of  $L_n$ . To avoid excessively long simulations, we removed any that lasted longer than  $n = 5000$ , but we found changing this upper bound did not affect averages considerably. There were 400 values of  $\theta$  chosen, discretizing the interval from  $\theta = 0$  to  $\theta = 3.89$ .

**A.3 Continuum Limit for Two States with Asymmetric Rates.** We begin by considering equation 4.8a, which provides an update of the probability of being in state  $H^1$  after  $n$  observations, given the specific change-point matrix  $\mathbf{a}$ :

$$\begin{aligned} P_n(H^1, \mathbf{a}) = \mathcal{F}_{n,\Delta t}^1 & \left[ \left( 1 - \frac{a^{21} + 1}{1 + a^{21} + a^{11}} \right) P_{n-1}(H^1, \mathbf{a} - \delta^{11}) \right. \\ & \left. + \frac{a^{12}}{1 + a^{12} + a^{22}} P_{n-1}(H^2, \mathbf{a} - \delta^{12}) \right], \end{aligned} \quad (\text{A.1})$$

where we have defined  $\mathcal{F}_{n,\Delta t}^1 = \frac{P(\xi_{1:n-1}^1)}{P(\xi_{1:n}^1)} f_{\Delta t}^1(\xi_n)$ . Subsequently, we divide by  $P_{n-1}(H^1, \mathbf{a})$  and take the logarithm to find

$$\begin{aligned} \Delta x_n^1(\mathbf{a}) = \ln \mathcal{F}_{n,\Delta t}^1 + \ln & \left[ \left( 1 - \frac{a^{21} + 1}{1 + a^{21} + a^{11}} \right) e^{x_{n-1}^1(a) - \delta^{11}} \right. \\ & \left. + \frac{a^{12}}{1 + a^{12} + a^{22}} e^{x_{n-1}^2(a) - \delta^{12}} \right]. \end{aligned}$$

Now, as we are taking the continuum limit, we consider  $P(H_{t+\Delta t} = H^\pm | H_t = H^\mp) = \epsilon^{ij} \Delta t + o(\Delta t)$ , where  $0 \leq \epsilon^{ij} < \infty$ . Given a  $\mathbb{R}^{2 \times 2}$  transition rate matrix with off-diagonal entries  $\epsilon^{ij} \Delta t + o(\Delta t)$  and diagonal entries  $1 - \epsilon^{ij} \Delta t + o(\Delta t)$ , the expected change-point and non-change-point counts after  $n$  time steps will be  $\langle a_{\Delta t}^{jj} \rangle = \Delta t \epsilon^{12} \epsilon^{21} n / (\epsilon^{12} + \epsilon^{21})$  and  $\langle a_{\Delta t}^{ii} \rangle = \epsilon^{ij} n / (\epsilon^{12} + \epsilon^{21})$ . Thus, while the change-point counts  $a_{\Delta t}^{ij}$  scale with  $\Delta t$ , the non-change-point counts do not. In the continuum limit, we will choose a time  $t := n \Delta t$  and take  $\Delta t \rightarrow 0$  while keeping  $t$  constant, so the number of time steps diverges like  $n = t / (\Delta t)$  for a fixed time  $t$ . While the expected change-point counts  $\langle a_{\Delta t}^{ij} \rangle$  thus remain fixed, the non-change-point counts  $\langle a_{\Delta t}^{ii} \rangle$  will diverge as  $(\Delta t)^{-1}$ , suggesting we should rescale non-change-point counts to the absolute dwell time  $t_{\Delta t}^i = \Delta t a_{\Delta t}^{ii}$ . The expected value of the dwell times is then finite in this limit  $\lim_{\Delta t \rightarrow 0} \langle t_{\Delta t}^i \rangle = \epsilon^{ij} t / (\epsilon^{12} + \epsilon^{21})$ . Performing this change of variables, we define the change-point matrix as involving change-point counts  $a^{ij}$  on the off-diagonal and dwell times along the

diagonal:  $A_t = \begin{pmatrix} t^1 & a_t^{12} \\ a_t^{21} & t^2 \end{pmatrix}$  so an increment of non-change-point count  $a^{ii}$  now takes the form  $A_t + \Delta t \delta^{ii}$ . As such, we can now expand

$$e^{x^i(a-\delta^{ii})} = e^{x^i(A_t - \Delta t \delta^{ii})} = e^{x^i(A_t)} - \Delta t e^{x^i(A_t)} \frac{\partial x^i(A_t)}{\partial t^i} + \mathcal{O}((\Delta t)^2)$$

via application of the chain rule and noting  $dt^i/da^{ii} = \Delta t$ . Note that we cannot perform such an expansion in  $\Delta t$  to  $x^i(A_t - \delta^{ij})$ , since perturbations to the matrix  $A_t$  in this case are  $\mathcal{O}(1)$ . Truncating equation A.1 to terms of  $\mathcal{O}(\Delta t)$  and incorporating the Poisson-delta prior equation 5.10, we find the discrete update equation becomes

$$\Delta x_n^1(A_t) = \ln \mathcal{F}_{n,\Delta t}^1 + \Delta t \cdot \left[ \frac{a_t^{12} + \alpha_2 - 1}{t^2 + \beta_2} e^{x_{n-1}^2(A_t - \delta^{12}) - x_{n-1}^1(A_t)} - \frac{a_t^{21} + \alpha_1}{t^1 + \beta_1} - \frac{\partial x_{n-1}^1(A_t)}{\partial t^1} \right].$$

Finally, on taking the continuum limit  $\Delta t \rightarrow 0$ , we find that

$$\begin{aligned} dx_t^1(A_t) &= [g_t^1 dt + dW_t^1] \\ &+ \left[ \frac{a_t^{12} + \alpha_2 - 1}{t^2 + \beta_2} e^{x_t^2(A_t - \delta^{12}) - x_t^1(A_t)} - \frac{a_t^{21} + \alpha_1}{t^1 + \beta_1} - \frac{\partial x_t^1(A_t)}{\partial t^1} \right] dt, \end{aligned}$$

where the statistics of the drift  $g_t^1$  and noise  $dW_t^1$  are analogous to those given after equation 5.6, only the transition rates of  $H_t$  from  $H^i \mapsto H^j$  are now  $\epsilon^{ij}$ . Due to the flux term  $\frac{\partial x_t^1(A_t)}{\partial t^1}$  and continuum values for  $t^j \in \mathbb{R}^*$ , this is a stochastic partial differential equation (SPDE). An analogous SPDE can be derived for  $x_t^2(A_t)$  in the same way.

**A.4 Continuum Limit with Multiple States and Symmetric Rates.** The derivation parallels that with two states. To obtain the continuum limit, we use the generalized version of equation 3.1:

$$\begin{aligned} P_n(H_n, a_n) &= \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} P(\xi_n | H_n) \sum_{H_{n-1}} \sum_{a_{n-1}=0}^{\infty} P_{n-1}(H_{n-1}, a_{n-1}) \\ &\times P(H_n, a_n | H_{n-1}, a_{n-1}). \end{aligned} \tag{A.2}$$

Assuming again a gamma prior on the transition rate,  $\epsilon \sim \text{Gamma}(\alpha, \beta)$ , and following the derivations of equations 3.18 and 5.4, we obtain

$$\begin{aligned}
 & P(H_n, a_n | H_{n-1}, a_{n-1}) \\
 &= \begin{cases} 1 - \Delta t \frac{a_n + \alpha}{t_{n-1} + \beta}, & \& : H_n = H_{n-1} \ \& a_n = a_{n-1} \\ \Delta t \frac{a_n + \alpha - 1}{(N - 1)(t_{n-1} + \beta)}, & \& : H_n \neq H_{n-1} \ \& a_n = a_{n-1} + 1 \\ 0, & \& : \text{otherwise.} \end{cases} \quad (\text{A.3})
 \end{aligned}$$

Using equation A.2 in equation A.3 yields

$$\begin{aligned}
 P_n(H^i, a) &= \frac{P(\xi_{1:n-1})}{P(\xi_{1:n})} f_{\Delta t}^i(\xi_n) \left[ \left( 1 - \Delta t \frac{a + \alpha}{t_{n-1} + \beta} \right) P_{n-1}(H^i, a) \right. \\
 &\quad \left. + \Delta t \frac{a + \alpha - 1}{(N - 1)(t_{n-1} + \beta)} \sum_{j \neq i} P_{n-1}(H^j, a - 1) \right].
 \end{aligned}$$

Dividing by  $P_{n-1}(H^i, a)$ , taking logarithms, and denoting  $x_t^i(a) := \ln P_n(H^i, a)$  we obtain

$$\begin{aligned}
 \Delta x_t^i(a) &\propto \ln f_{\Delta t}^i(\xi_n) \\
 &+ \ln \left[ 1 - \Delta t \frac{a + \alpha}{t_{n-1} + \beta} + \Delta t \frac{a + \alpha - 1}{(N - 1)(t_{n-1} + \beta)} \sum_{j \neq i} e^{x_{t_{n-1}}^j(a-1) - x_{t_{n-1}}^i(a)} \right].
 \end{aligned}$$

Using the approximation  $\ln(1 + z) \approx z$  valid for small  $z$  yields

$$\begin{aligned}
 \Delta x_t^i(a) &\propto \ln f_{\Delta t}^i(\xi_n) \\
 &+ \Delta t \left( \frac{a + \alpha - 1}{(N - 1)(t_{n-1} + \beta)} \sum_{j \neq i} e^{x_{t_{n-1}}^j(a-1) - x_{t_{n-1}}^i(a)} - \frac{a + \alpha}{t_{n-1} + \beta} \right).
 \end{aligned}$$

Similar to the  $N = 2$  case, we may then take the continuum limit to yield equation 5.12.

**A.5 Consistency of the Moment Hierarchy Equations.** We begin by taking the SDE given by equation 2.2 for  $N = 2$  states, and the known rate  $\epsilon$  and changing variables to  $\bar{P}_t^\pm = e^{x_t^\pm}$ , so

$$d\bar{P}_t^\pm = \bar{P}_t^\pm [g_t^\pm dt + dW^\pm] + \epsilon [\bar{P}_t^\mp - \bar{P}_t^\pm] dt.$$

Furthermore, note that in the limit  $t \rightarrow \infty$ , the  $\mathcal{O}(1)$  terms and  $\mathcal{O}(t^{-1})$  terms vanish in equation 5.16:

$$d\bar{P}_t^\pm = \bar{P}_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW^\pm \right] + [\bar{A}_t^\mp - \bar{A}_t^\pm] dt \quad (\text{A.4a})$$

$$d\bar{A}_t^\pm = \bar{A}_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW^\pm \right] + (\bar{A}_t^\mp - \bar{A}_t^\pm) (\bar{A}_t^\mp + \bar{A}_t^\pm) dt. \quad (\text{A.4b})$$

Therefore, in the event that  $\bar{A}_t^\pm \rightarrow \epsilon \bar{P}_t^\pm$  in the long time limit ( $t \rightarrow \infty$ ), we find the truncated system, equation A.4, becomes

$$d\bar{P}_t^\pm = \bar{P}_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW^\pm \right] + \epsilon \cdot [\bar{P}_t^\mp - \bar{P}_t^\pm] dt \quad (\text{A.5a})$$

$$\epsilon d\bar{P}_t^\pm = \epsilon \bar{P}_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW^\pm \right] + \epsilon^2 \cdot (\bar{P}_t^\mp - \bar{P}_t^\pm) (\bar{P}_t^\mp + \bar{P}_t^\pm) dt. \quad (\text{A.5b})$$

Dividing by  $\epsilon$  and noting that  $\bar{P}_t^+ + \bar{P}_t^- = 1$ , equation A.5 becomes

$$d\bar{P}_t^\pm = \bar{P}_t^\pm \left[ \left( g_t^\pm + \frac{1}{2} \right) dt + dW^\pm \right] + \epsilon \cdot [\bar{P}_t^\mp - \bar{P}_t^\pm] dt,$$

which is consistent with equation A.5, and indicates the truncated moment hierarchy is consistent with the case of known rates and two choices ( $N = 2$ ) in the SDE, equation 2.2.

**A.6 Noise-Free Limit of the Neural Population Model.** Consider the neural population (see equation 6.1a) for the evolution of  $u_t^-$  in the event of environmental state  $H_t = H^+$  and no observation noise  $f^\pm(\xi|H^+) = \delta(\xi - \xi^\pm)$ . As a result, the drift terms diverge  $g_t^\pm := \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \mathbb{E}[\ln f_{\Delta t}^\pm(\xi)|H^+] \rightarrow \pm\infty$  and the covariance matrix  $\Sigma_t^{ij} := \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \text{Cov}[\ln f_{\Delta t}^i(\xi), \ln f_{\Delta t}^j(\xi)|H^+] \rightarrow 0$ . Thus, the dominant terms on the right-hand side of equation 6.1a for  $u_t^-$  come from the input so  $du_t^- = -u_t^- |g^-| dt$ , and the population activity immediately decays to  $u_t^- = 0$ . As a result, since  $u_t^+ + u_t^- = 1$ , we expect  $u_t^+ = 1$ , when  $H_t = H^+$ .

**A.7 Performance of the Neural Population Model.** In Figure 8, we compare the performance (percentage of correct responses) of the full SDE model, equation 5.7, to the moment closure approximation, equation 5.16, and the neural population model, equation 6.7, where we have made a weak noise approximation. As in Figure 3A, we employ the interrogation protocol, where the observer reports the predicted state of the environment

Figure 8: The performance of the neural population model, equation 6.7, in comparison to the full SDE model, equation 5.7, and the moment closure approximation, equation 5.16. Performance is tested under the interrogation paradigm and defined as the percentage of correct responses at the interrogation time. Here  $\epsilon = 0.05$  and  $\text{SNR} = 1$ . The black curve represents the performance of the full SDE model given by equation 5.7, an ideal observer who takes measurements continuously to infer the change rate. The blue dashed curve represents the performance of the moment closure model, equation 5.16, where we have truncated as shown in section 5.2. Finally, the performance of the neural population model, equation 6.7, is represented by the red dotted curve. Simulation parameters are given in section 7.9.

at a fixed time. In both the full model (black solid line) and the moment closure model (blue dashed line), performance increases with time. On the other hand, there is a slight decrease in the performance of the neural population model (red dotted line) with time, suggesting that its estimate of the change rate may be corrupted by noise in a way that is not captured by our truncation. Regardless, all three models have relatively similar performance.

**A.8 Neural Populations Corresponding to Log Probabilities.** In Veliz-Cuba et al. (2016), we derived a neural population model for optimal evidence accumulation when the environmental change rate is known. In contrast to our population rate model, this set of equations described neural population rates in terms of the log probability of an environmental state, rather than the probability. For comparison with Veliz-Cuba et al. (2016) and other previous neural population models of evidence accumulation in static environments (Bogacz et al., 2006; McMillen & Holmes, 2006), we map our equations to an equivalent system where the population rates correspond to log probabilities. To do so, we make the change of variables  $u_t^\pm = e^{x_t^\pm}$  so that  $du_t^\pm = e^{x_t^\pm} dx_t^\pm = u_t^\pm dx_t^\pm$ . As in section 5.1, Itô's change of coordinates

rules (Gardiner, 2004) imply our population model is equivalent to

$$dx_t^\pm = I_t^\pm dt + dW_t^\pm + [w_t^\mp e^{x_t^\mp - x_t^\pm} - w_t^\pm]dt,$$

$$dw_t^\pm = [\delta(x_t^+ - x_t^-) - w_t^\pm] \cdot C_t dt.$$

Although the delta distribution  $\delta(x_t^+ - x_t^-)$  should technically be rescaled to account for its composition with  $e^x$ , we ignore this transformation (Keener, 1988), since the increment produced from the delta distribution models the change-point counting process. Thus, each event where  $x_t^+ = x_t^-$  (equivalently  $u_t^+ = u_t^-$ ) should be counted the same in the log-probability equations as in the probability equations.

**A.9 Numerical Simulations of SDE Models.** Stochastic differential equation (SDE) models of evidence accumulation in symmetric environments changing between two states are simulated using a standard Euler-Maruyama integration algorithm (Higham, 2001). Equation 5.7 describes the evolution of an infinite number of SDEs over the change point vector  $a \in \mathbb{Z}_{\geq 0}$ , state vector  $H_t \in \{H^+, H^-\}$ , and time  $t \in [0, T]$ , so we truncate this space to  $a \in \{0, 1, 2, \dots, 1000\}$ , which is sufficient for transition rates  $\epsilon$  and total simulation times  $T$  not too large. We compared our results to cases with longer state vectors  $a \in \{0, 1, 2, \dots, a_{\max}\}$ , and the changes were negligible. Simulations shown in Figure 6 had a transition rate of  $\epsilon = 0.1$  and total run time of  $T = 1000$  with time step  $dt = 10^{-3}$ . Observations were sampled from a normal distribution  $f^\pm(\xi) = \frac{e^{-(\xi \mp \mu)^2 / (2\sigma^2)}}{\sqrt{2\pi\sigma^2}}$  with mean  $\mu = 0.5$  and variance  $\sigma^2 = 1$ , so the signal-to-noise ratio was  $2\mu/\sigma = 1$ . Initial conditions were chosen so that  $P_0^\pm = 0.5$  and  $P_0(a) = \frac{\alpha^a e^{-\alpha}}{a!}$  where  $\alpha = 1$  and  $\beta = 5$ . A similar approach was used to numerically simulate the neural population model, equation 6.7, and its variants to produce Figure 7 ( $\mu = 1$  and  $\sigma = 0.1$ ) and Figure 8 ( $\mu = 0.5$  and  $\sigma^2 = 1$ , for consistency with the full equation 5.7 and equation 5.16).
