## ABSTRACT

A modified extended finite element method (XFEM) for dynamic fracture is presented with a new methodology to construct the XFEM basis for discontinuities. In this method, the enrichment bases are defined to capture the characteristic discontinuities across the interface. The enrichments are vanished outside the element domain so that no blending of the local partition unity is required. The enrichment parameters effectively represent the physics of the discontinuity and are assigned to non-nodal points, which helps to impose Dirichlet boundary conditions on the interface. This feature successfully dissociates the finite element nodes from the extended finite element approximation; it facilitates the treatment of arbitrary crack propagation in explicit methods. The approach is applied to linear three-node triangular elements for element-by-element crack propagation modeling. The proposed method combined with explicit time integration and a cohesive law can successfully predict the dynamic fracture of ductile and brittle materials. Dynamic simulation results in terms of crack path and speed were effectively computed and match the experimental results. Through these numerical examples, the robustness and performance of the method were successfully demonstrated.

## 1. Introduction

The extended finite element method (XFEM) [1,2] can be viewed as a variation of the generalized finite element method (GFEM) introduced by Melenk and Babuška [3] whereby arbitrary discontinuities such as cracks and shear bands can be modeled without remeshing. One advantage of the XFEM over the GFEM is that it permits the use of local enrichment bases in the finite element (FE) approximation. For the FE convergence, completeness is a necessary condition, i.e. the local approximation must be capable of reproducing given smooth functions, which for elasticity are rigid body motions and constant strain states. However, the local approximation in conventional XFEM focuses only on reproducing the discontinuous functions along with satisfying compatibility condition among enriched and its contiguous elements. Therefore, in many instances, it is not apparent how to be the XFEM convergence rates.

The XFEM exploits the partition of unity framework to adopt various functions as a basis for reproducing the discontinuous fields; step enrichment functions for strong discontinuity [4], asymptotic crack-tip functions for crack tip modeling [1], distance enrichment functions for weak discontinuities [5,6] and hyperbolic tangent enrichment functions

for discontinuities in derivatives [7]. Furthermore, The XFEM has successfully been applied to many other applications; cohesive crack models [8,9], evolution of dislocations [10,11] and modeling of grain boundaries [12]. In addition, the XFEM and GFEM provided a crucial insight for meshless methods [13,14] involving the dynamic fracture simulations. Although in these approaches, the extended approximation effectively captures the discontinuity, it may not be able to reproduce the polynomial functions required for completeness.

One of the main challenges arisen in using XFEM is the implementation; to circumvent such difficulties, several alternative approaches have been developed [15–20] to enable robust and efficient failure modeling. In conventional XFEM, the enrichment part generally spreads over the elements contiguous to the enriched element. These elements are often called blending elements and should be treated appropriately [21]. For step enrichment functions, the blending regions can be avoided by shifting enrichment techniques introduced by Zi and Belytschko [9]. Furthermore, in conventional XFEM, the enrichment parameters are assigned to element nodes which are often in common among several elements. This feature violates the local description of enrichment part which dramatically facilitates the XFEM implementation. Therefore, it is desirable to have a technique that can define an

enrichment independent from element nodes.

The main objective of the proposed method is to develop a highly efficient XFEM basis but nevertheless quite accurate formulation for discontinuity modeling. The proposed method considers a set of non-nodal points on the interface whereby it can capture the discontinuities in a function and its derivatives across the interface. In this method, the enrichment parameters are selected as *physically-based* quantities associated to the discontinuity of the problem whereby the Dirichlet boundary conditions can be simply imposed on element edges and the surfaces of discontinuity. Moreover, the associated enrichment functions are constructed so that they vanish on element edges. This feature leads to an enrichment fully defined in a local domain, which dramatically simplifies the XFEM implementation. Hence, it is conceivable to think that the proposed method can be an effective scheme for reproducing discontinuities in an XFEM framework.

An outline of the paper is as follows. In Section 2, we shall first review the conventional XFEM, and then describe the new methodology for constructing enrichment functions where the discontinuous displacement field is modeled by non-nodal enrichment parameters. In Section 3, we set up the governing equations and present the weak form and the discretization for the dynamic fracture simulation. Section 4 describes the cohesive law and cohesive crack model. Finally, in Sections 5 and 6, numerical studies and concluding remarks are presented.

## 2. Enriched displacement fields for discontinuity

Let us consider a two-dimensional domain  $\Omega_0 \in \mathbb{R}^2$  with its boundary  $\Gamma^0$  in the reference configuration as shown in Fig. 1. The material and spatial coordinates are respectively denoted by  $\mathbf{X}$  and  $\mathbf{x}$  with the motion described by  $\mathbf{x} = \mathbf{u}(\mathbf{X}, t)$ . The current images of  $\Omega_0$  and  $\Gamma^0$  are denoted by  $\Omega$  and  $\Gamma$ , respectively. The entire boundary  $\Gamma^0$  is partitioned into either the essential boundary  $\Gamma_u^0$  or the natural boundary  $\Gamma_t^0$  such that  $\Gamma_u^0 \cap \Gamma_t^0 = \emptyset$  and  $\Gamma_u^0 \cup \Gamma_t^0 = \Gamma^0$ .

To construct enrichment functions in the XFEM framework, an accurate description of the interface is often useful. The interface, i.e. the crack surface in this study, can be implicitly defined by a set of level set functions as

$$\mathbf{X} \in \Gamma_c^0 \text{ if } f(\mathbf{X}) = 0 \text{ and } g(\mathbf{X}, t) > 0 \quad (1)$$

As shown in Fig. 2, the signed distance function  $f(\mathbf{X})$  can be described by

$$f(\mathbf{X}) = \min_{\bar{\mathbf{X}} \in \Gamma_c^0} \|\mathbf{X} - \bar{\mathbf{X}}\| \text{ sign}(\mathbf{n}^+ \cdot (\bar{\mathbf{X}} - \mathbf{X})) \quad (2)$$

where  $\bar{\mathbf{X}}$  is the closest point on the interface to  $\mathbf{X}$  and  $\|\cdot\|$  denotes the Euclidean norm.  $g(\mathbf{X}, t)$  is defined such that the crack is enclosed within the subdomain  $g(\mathbf{X}, t) \geq 0$  whereas the crack tip is located by  $g(\mathbf{X}, t) = 0$ . For discretized domains, the evaluation of the implicit function  $f(\mathbf{X})$  can be simplified by finite element discretizations and is then defined by

$$f(\mathbf{X}) = \sum_I f_I N_I(\mathbf{X}) \quad (3)$$

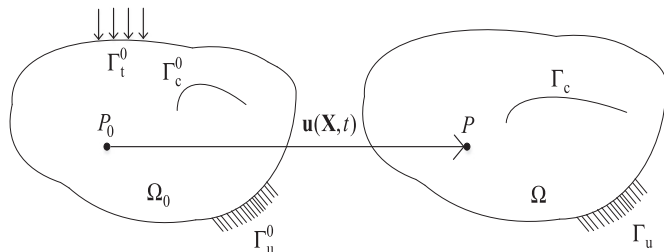

Fig. 1. A two-dimensional domain and its current configuration with a crack.

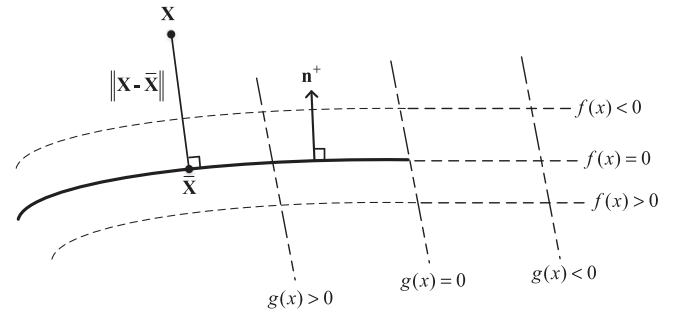

Fig. 2. Crack representation by two level set functions  $f$  and  $g$ .

Furthermore, the derivatives of the level set functions which are useful in the cohesive force computations can be simply computed by finite element approximations as

$$f(\mathbf{X})_{,i} = \sum_I f_I N_{I,i}(\mathbf{X}) \quad (4)$$

A strong discontinuity in a function, i.e. a displacement jump in crack modeling, can be represented by the Heaviside step function. The Heaviside step function can be also defined in terms of the level set function  $f$  given by

$$H(f(\mathbf{X})) = \begin{cases} 0 & f(\mathbf{X}) < 0 \\ 1 & f(\mathbf{X}) > 0 \end{cases} \quad (5)$$

In conventional XFEM, the discontinuous function itself is used as the enrichment function and the partition of unity enables the approximation to reproduce the discontinuous function exactly by satisfying

$$\sum_{I=1}^{n_e} N_I(\mathbf{X}) \Phi(\mathbf{X}) = \Phi(\mathbf{X}) \quad (6)$$

where  $\Phi$  can be any discontinuous functions. However, in the presented method, the enrichment functions are associated to the non-nodal points and are defined so that they can reproduce the discontinuity without local partition of unity, i.e. the enrichment functions are not multiplied by standard shape functions  $N_I$ , and consequently the element nodes are not enriched. In a vector form, the displacement field can then be defined as following:

$$\begin{aligned} \mathbf{u}(\mathbf{X}, t) &= \mathbf{u}^{\text{FEM}}(\mathbf{X}, t) + \mathbf{u}^{\text{ENRICHED}}(\mathbf{X}, t) \\ &= \sum_{I=1}^{n_e} N_I(\mathbf{X}) \mathbf{u}_I(t) + \sum_{J \in \delta_{\text{en}}} \Psi_J(\mathbf{X}) \mathbf{a}_J(t) \end{aligned} \quad (7)$$

where  $\delta_{\text{en}}$  is the set of non-nodal enriched points (usually on crack path in two dimensions) and  $\mathbf{a}_J$  are the additional degrees of freedom associated with their enrichment function  $\Psi_J$ . In the following, first we will describe the crack modeling procedure in two dimensions for a constant strain triangular element, then we will briefly illustrate extending the formulation to both a general discontinuous function and a multi-dimensional multi-node finite element.

### 2.1. Representation of a crack with non-nodal enrichment parameters for 3-node triangular elements

In this section, we will describe the crack modeling procedure in two dimensions for a constant strain triangular element. We only consider the elements that are completely cut by a crack, i.e., a crack propagates one complete element at a time so that the crack tip is always placed on element edges. Let us consider a finite element with the local node numbers as shown in Fig. 3(a). The crack is assumed to be straight within the element; it has advanced from the surface  $S_3$  to the surface  $S_1$  so that  $\mathbf{X}_1^c$  and  $\mathbf{X}_2^c$  are the first and second intersection points between the crack and element edges, respectively.

The enrichment variables in crack modeling are considered as jumps

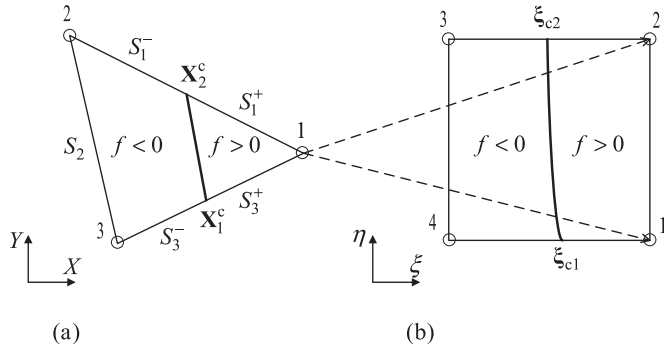

Fig. 3. Duffy's mapping between (a) a triangular element in material coordinates and (b) a biunit square in parent coordinates  $-1 \leq \xi \leq 1$ ;  $-1 \leq \eta \leq 1$ .

in the functions at the non-nodal points; in Fig. 3(a), the jump in displacement at  $\mathbf{X}_1^c$  and  $\mathbf{X}_2^c$  are denoted by  $[[\mathbf{u}]]_1$  and  $[[\mathbf{u}]]_2$ , respectively. Thus, the approximation is

$$\begin{aligned} \mathbf{u}(\mathbf{X}, t) &= \sum_{I=1}^{n_e} N_I(\mathbf{X}) \mathbf{u}_I(t) + \sum_{J=1}^2 \Psi_J(\mathbf{X}) [[\mathbf{u}(t)]]_J \\ &= \sum_{I=1}^{n_e} N_I(\mathbf{X}) \mathbf{u}_I(t) + \Psi_1(\mathbf{X}) [[\mathbf{u}(t)]]_1 + \Psi_2(\mathbf{X}) [[\mathbf{u}(t)]]_2 \end{aligned} \quad (8)$$

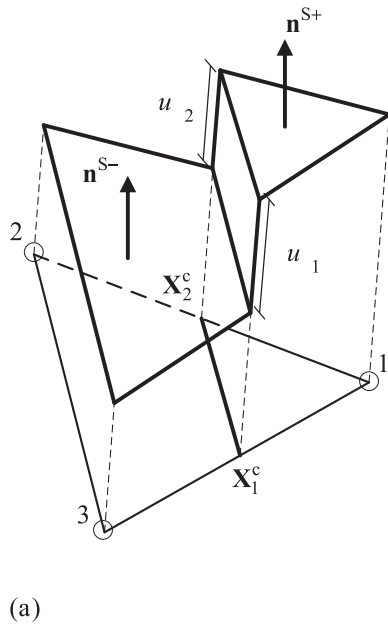

where the enrichment variables  $[[\mathbf{u}]]_1$  and  $[[\mathbf{u}]]_2$  for a scalar component are illustrated in Fig. 4(a).

We construct the enrichment functions so that the approximation in Eq. (8) can reproduce the characteristic function, i.e. the Heaviside step function in Eq. (5). Thus, by substituting the displacement field  $\mathbf{u}$  with the vectorized  $\mathbf{H}$ , Eq. (8) can be rewritten as

$$\mathbf{H}(\mathbf{X}, t) = \sum_{I=1}^{n_e} N_I(\mathbf{X}) \mathbf{H}_I(t) + \Psi_1(\mathbf{X}) [[\mathbf{H}(t)]]_1 + \Psi_2(\mathbf{X}) [[\mathbf{H}(t)]]_2 \quad (9)$$

For the assumed direction of the crack illustrated in Fig. 3,  $\mathbf{H}_1 = 1$ ,  $\mathbf{H}_2 = \mathbf{H}_3 = 0$  and  $[[\mathbf{H}]]_{\mathbf{X} \in \Gamma_c} = 1$ . Considering  $\sum_{I=1}^{n_e} N_I = 1$  and by partitioning Eq. (9) for each side of the interface, we have

$$\begin{aligned} \Psi_1^+(\mathbf{X}) + \Psi_2^+(\mathbf{X}) &= N_2 + N_3 \\ \Psi_1^-(\mathbf{X}) + \Psi_2^-(\mathbf{X}) &= -N_1 \end{aligned} \quad (10)$$

It is important to note that finding any sets of enrichment functions that satisfies Eq. (10) enables the extended approximation to reproduce the discontinuous function. However, Eq. (10) does not satisfy the  $C^0$  continuity condition among enriched element and its contiguous elements. Therefore, the enrichment functions are defined to be vanished along specific element edges. For instance, in the first equation,  $\Psi_1^+$  and  $\Psi_2^+$  must vanish along surfaces  $S_1^+$  and  $S_3^+$  as shown in Fig. 3(a), respectively. Thus, we simply assign  $\Psi_1^+ = N_3$  and  $\Psi_2^+ = N_2$ . However in the second equation  $\Psi_1^-$  must vanish along both surfaces  $S_1^-$  and  $S_2$ , and also  $\Psi_2^-$  must vanish along surfaces  $S_3^-$  and  $S_2$ . To facilitate the construction of such enrichment functions, the Duffy transformation which is a mapping from a square to a triangle can be used; the Duffy transformation can be viewed as a mapping from a square in parent coordinates to a triangle in material coordinate as illustrated in Fig. 3. A detailed description of the Duffy transformation can be found in [22–24].

In this transformation, one vertex in the triangle is mapped to an edge in the square. This vertex is chosen such that the crack passes through non-adjacent edges in parent domain. Therefore, this node should be the node opposite to the edge that is not intersected by the crack, which is node 1 here (See Fig. 3(a)). Then, the FE approximation is given by

$$\mathbf{u}(\mathbf{X}, t) = \sum_{I=1}^{n_e} N'_I(\mathbf{X}) \mathbf{u}_I(t) \quad (11)$$

where the Duffy isoparametric shape functions can be expressed in terms of standard bilinear shape functions as

$$\begin{aligned} N'_1 &= N_1^{4Q} + N_2^{4Q} \\ N'_2 &= N_3^{4Q} \\ N'_3 &= N_4^{4Q} \end{aligned} \quad (12)$$

where

$$N_i^{4Q}(\xi, \eta) = \frac{1}{4}(1 + \xi_i \xi)(1 + \eta_i \eta) \quad (13)$$

Here,  $(\xi, \eta)$  are nodal coordinates of bi-unit square shown in Fig. 3(b). By substituting the shape functions in Eq. (12) into Eq. (10), we can obtain

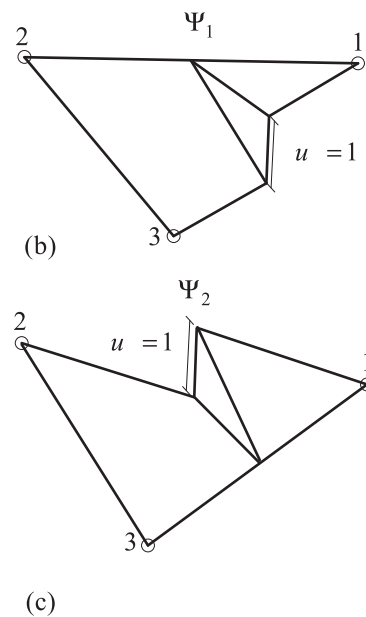

Fig. 4. The enrichment parameters and their associated enrichment functions: (a) the representation of a discontinuity in a two-dimensional model;  $\mathbf{n}^{S+}$  and  $\mathbf{n}^{S-}$  are normal to the interpolation surfaces; (b) the enrichment function  $\Psi_1$  associated to the non-nodal point  $\mathbf{X}_1^c$ ; and (c) the enrichment function  $\Psi_2$  associated to the non-nodal point  $\mathbf{X}_2^c$ .

$$\begin{aligned}\Psi_1^+ + \Psi_2^+ &= N_3^{4Q} + N_4^{4Q} \\ \Psi_1^- + \Psi_2^- &= -N_1^{4Q} - N_2^{4Q}\end{aligned}\quad (14)$$

Thus, the  $C^0$  continuity condition is simply satisfied by assigning the enrichment functions as follows

$$\begin{aligned}\Psi_1 &= \begin{cases} -N_1^{4Q} & f < 0 \\ N_4^{4Q} & f > 0 \end{cases} \\ \Psi_2 &= \begin{cases} -N_2^{4Q} & f < 0 \\ N_3^{4Q} & f > 0 \end{cases}\end{aligned}\quad (15)$$

It is important to note that the enrichment functions obtained by the Duffy transformation are in terms of well-known bilinear shape functions. So, one can extensively make use of existing codes for the calculation of the enrichment functions and their derivatives. However, some more code implementation is required to implement the Duffy interpolation.

The enrichment functions in Eq. (15) are shown in Fig. 4(b) and (c). As it can be seen, the enrichment functions have a jump equal to the unity at their associated non-nodal point. The interpolation given in Eq. (8), in addition to the Heaviside step function, can reproduce two planes shown in Fig. 4(a) that their unit normal to the surface of the interpolation are parallel, i.e.

$$\mathbf{n}^{S-} \times \mathbf{n}^{S+} = \mathbf{0} \quad (16)$$

The detailed proof has been provided in Appendix A. However, such a discontinuity modeling is sufficient for failure modeling in homogeneous linear elastic materials since the stresses and strains at both sides of the crack are equal during the failure process due to the fact that both sides of the crack should satisfy traction free condition (or be subjected to equal but in opposite normal cohesive traction). Modeling discontinuity in derivative fields will remain as a future work.

The relations between the bilinear Duffy shape functions and the standard triangle shape functions are obtained in Appendix B. Thus, the enrichment functions can be also expressed in terms of standard shape functions as

$$\begin{aligned}\Psi_1 &= \begin{cases} -\frac{N_1 \times N_3}{N_2 + N_3} & f < 0 \\ N_3 & f > 0 \end{cases} \\ \Psi_2 &= \begin{cases} -\frac{N_1 \times N_2}{N_2 + N_3} & f < 0 \\ N_2 & f > 0 \end{cases}\end{aligned}\quad (17)$$

## 2.2. General formulations of the non-nodal enrichment XFEM

In this section, we briefly describe the extension of the method for a multi-dimensional multi-node finite element with a general discontinuous function  $\Phi(\mathbf{X})$ . The discontinuous function is defined as a function of level set function as

$$\Phi(\mathbf{X}) = F(f(\mathbf{X})) \quad (18)$$

As discussed in previous section, Eq. (7) can reproduce the discontinuous function  $\Phi$ , if it holds for  $\mathbf{u} = \Phi$ . Thus, Eq. (7) gives

$$\Phi(\mathbf{X}) = \sum_{I=1}^{n_e} N_I(\mathbf{X})\Phi(\mathbf{X}_I) + \sum_{J \in \delta_{\text{en}}} \Psi_J(\mathbf{X})\mathbf{a}_J \quad (19)$$

By rewriting Eq. (19) for either side of the interface separately we have

$$\begin{aligned}\Phi^+(\mathbf{X}) &= \sum_{I=1}^{n_e} N_I(\mathbf{X})\Phi(\mathbf{X}_I) + \sum_{J \in \delta_{\text{en}}} \Psi_J^+(\mathbf{X})\mathbf{a}_J \\ \Phi^-(\mathbf{X}) &= \sum_{I=1}^{n_e} N_I(\mathbf{X})\Phi(\mathbf{X}_I) + \sum_{J \in \delta_{\text{en}}} \Psi_J^-(\mathbf{X})\mathbf{a}_J\end{aligned}\quad (20)$$

The first terms on the right-hand side of Eq. (20) can also be partitioned for sides of the interface as

$$\sum_{I=1}^{n_e} N_I(\mathbf{X})\Phi(\mathbf{X}_I) = \sum_{I \in \delta_n^-} N_I(\mathbf{X})\Phi^-(\mathbf{X}_I) + \sum_{I \in \delta_n^+} N_I(\mathbf{X})\Phi^+(\mathbf{X}_I) \quad (21)$$

where  $\delta_n^+$  and  $\delta_n^-$  are the sets of element nodes that are on the sub-domains where  $f > 0$  and  $f < 0$ , respectively.

In this study, we assume that the discontinuous functions at either side of the interface, i.e.  $\Phi^+$  and  $\Phi^-$  are as sufficiently smooth as to be interpolated by standard shape functions. For example, the strong and weak discontinuities are often captured with the Heaviside and distance functions, respectively. This indicates that the enrichment functions are constant or linear on both sides of the interface and therefore, can be exactly interpolated by linear shape functions. So,  $\Phi^+$  and  $\Phi^-$  can be reproduced by finite element shape functions

$$\begin{aligned}\Phi^+(\mathbf{X}) &= \sum_{I=1}^{n_e} N_I(\mathbf{X})\Phi^+(\mathbf{X}_I) \\ \Phi^-(\mathbf{X}) &= \sum_{I=1}^{n_e} N_I(\mathbf{X})\Phi^-(\mathbf{X}_I)\end{aligned}\quad (22)$$

Substituting Eqs. (21) and (22) into (20), we will have

$$\begin{aligned}\sum_{I \in \delta_n^-} N_I(\mathbf{X})[[\Phi]]_{\mathbf{X}=\mathbf{X}_I} &= \sum_{J \in \delta_{\text{en}}} \Psi_J^+(\mathbf{X})\mathbf{a}_J \\ \sum_{I \in \delta_n^+} -N_I(\mathbf{X})[[\Phi]]_{\mathbf{X}=\mathbf{X}_I} &= \sum_{J \in \delta_{\text{en}}} \Psi_J^-(\mathbf{X})\mathbf{a}_J\end{aligned}\quad (23)$$

where  $[[\Phi]]_{\mathbf{X}} = \Phi^+(\mathbf{X}) - \Phi^-(\mathbf{X})$  is the jump in the left and right sides of the enrichment function at  $\mathbf{X}$ . Note that Eqs. (23) are the key equations used to construct the enrichment functions. It must be stressed that these equations do not suffice to provide closure to the definition of the enrichment functions. In other words, there are no unique enrichment functions and enrichment parameters that satisfy Eqs. (23). The overall procedure to define the enrichments can be organized using the following main steps:

1. Identifying the characteristic function (denoted by  $\Phi$  here) using a priori knowledge about the discontinuity in the problem.
2. Introducing the enrichment parameters which are best able to represent the identified discontinuity.
3. Defining the enrichment parameters and their associated enrichment functions so that they satisfy the following conditions:
  - (a) Eq. (23).
  - (b) The  $C^0$  continuity condition between the enriched element and its contiguous elements.

Note that the enrichment functions for triangular elements obtained in previous section can be simply attained using the aforementioned procedure. As an example, crack modeling in one dimension has been demonstrated in Appendix C.

## 2.3. Comparison to conventional XFEM

Some methodological issues of the conventional XFEM addressed by the non-nodal enrichment method are briefly described:

- The local partition of unity given in Eq. (6) only builds a partition of unity over reproducing elements for which all element nodes are enriched; see References [21,25–27] for more details. Due to mesh constraints, some of the element nodes may not be enriched for an element completely cut by a crack; these elements are often called blending elements. An example has been depicted in Fig. 5, where a crack has advanced through several elements and the crack tip is on the intersection of elements  $e_4$  and  $e_5$ . To satisfy  $C^0$  continuity condition, the nodes placed on the crack tip edge are selected not to be enriched as follows in Fig. 5, which leads to an unenriched node  $I$ . Thus, although the crack has crossed over the elements  $e_1$  through  $e_4$ , these elements are not still reproducing elements. In contrast to conventional XFEM, in non-nodal enrichment method, the element becomes a reproducing element as soon as the crack passes through it.

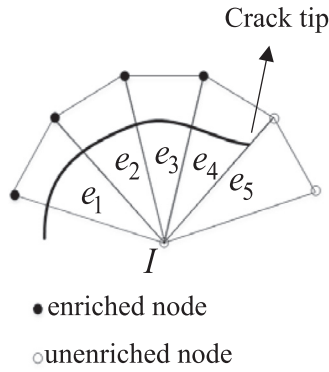

Fig. 5. A crack path on several elements which are not still reproducing elements because the enrichment is not added to node I..

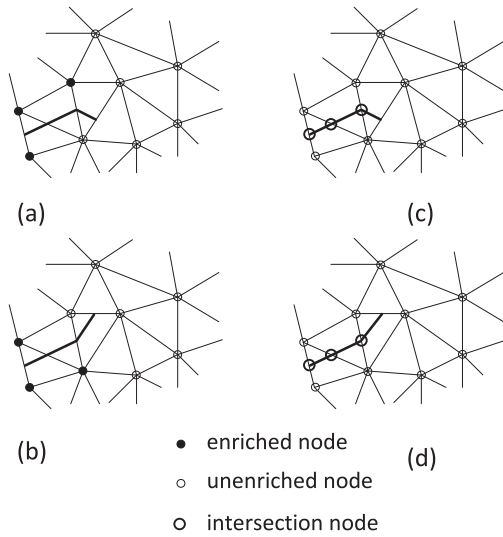

Fig. 6. Selection of enriched nodes: (a)-(b) in the conventional XFEM where enriched nodes are dependent on the direction of crack; and (c)-(d) in the proposed method where the FE nodes are not enriched but an enrichment variable is assigned to each intersection point.

- The conventional XFEM approximations do not, in general, satisfy the Kronecker- $\delta$  property that leads to difficulties in imposition of Dirichlet boundary conditions on enriched nodes. As proposed in References [5,9], the Kronecker- $\delta$  property can be achieved by shifting enrichment functions with respect to element nodes. However, shifting enrichment functions renders the construction of lumped mass matrix difficult which is crucial for efficient dynamic analysis. In the proposed method, the enrichment functions are vanished on element edges and consequently the Kronecker- $\delta$  property is essentially satisfied.
- Although the shifted enrichment functions hold Kronecker- $\delta$  property, they may not vanish on parts of element boundaries, and consequently spread over contiguous elements. This may influence the imposition of Dirichlet boundary conditions on element edges. Moreover, to preclude the parasitic terms added to the approximation, the contiguous elements which are often called blending elements are required to be treated appropriately. However, in the proposed method, the enrichment functions are vanished outside the element domains and consequently no blending elements appear.
- In conventional XFEM, the interpretation of the enrichment parameters is difficult so that the non-smooth Dirichlet boundary conditions and interface conditions may not be easily imposed on enrichment parameters. One of the main Dirichlet boundary conditions imposed on the contact interface is impenetrability

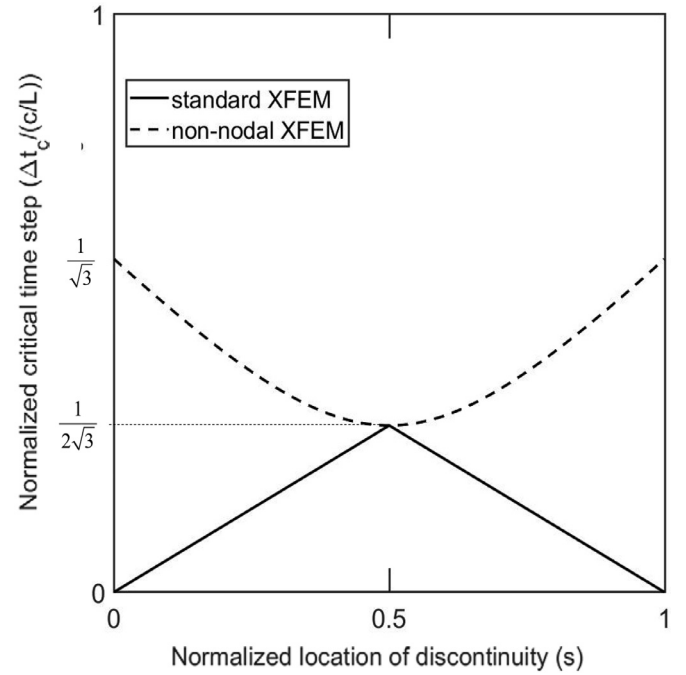

Fig. 7. The variation of normalized critical time step size according to the normalized location of the discontinuity.

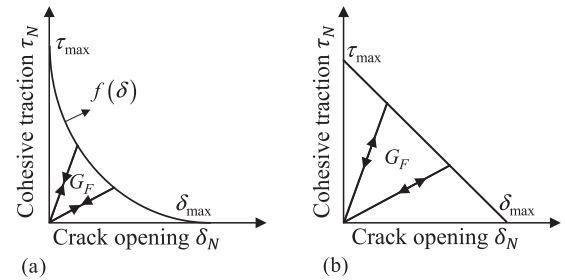

Fig. 8. Cohesive law; the area under the cohesive law curve is the same as the fracture energy (a) a general cohesive law; and (b) a linear cohesive law.

condition. In non-nodal enrichment method, the impenetrability condition can be easily applied as a Dirichlet boundary condition in the strong form as

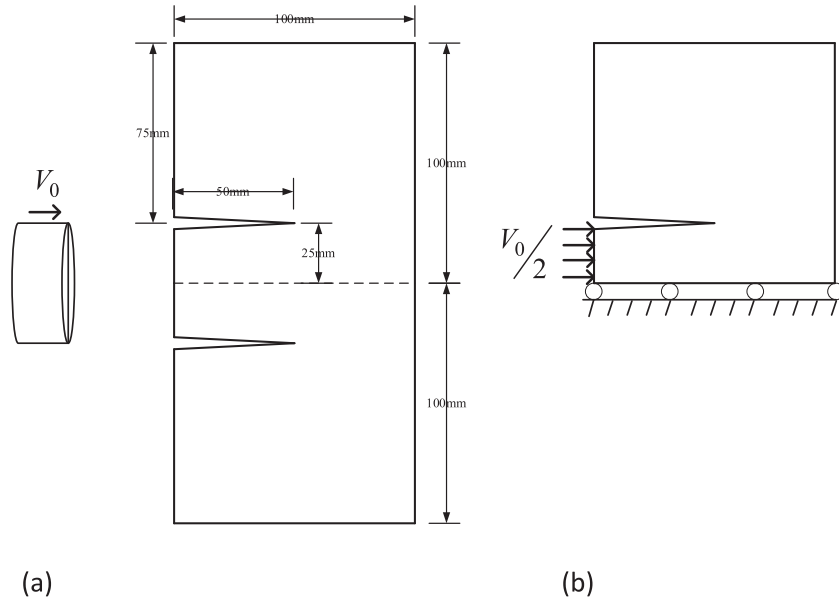

$$\text{if} [[\mathbf{u}]] = 0, \quad [[\dot{\mathbf{u}}]] \cdot \mathbf{n} \geq 0 \quad (24)$$

- In the conventional XFEM, the enriched nodes are chosen based on both the direction of the crack growth and whether it is contiguous to an existing crack or not. As shown in Fig. 6(a) and (b), the set of enriched nodes is dependent on the crack directions. However, in the presented method, enriching procedure depends on neither the crack direction nor the elements contiguous to the enriched element which indeed facilitates the crack modeling in an object-oriented program. As shown in Fig. 6(c) and (d), wherever a crack passes over an edge, one enrichment variable assigned to the intersection point is added to the enrichment variable set.

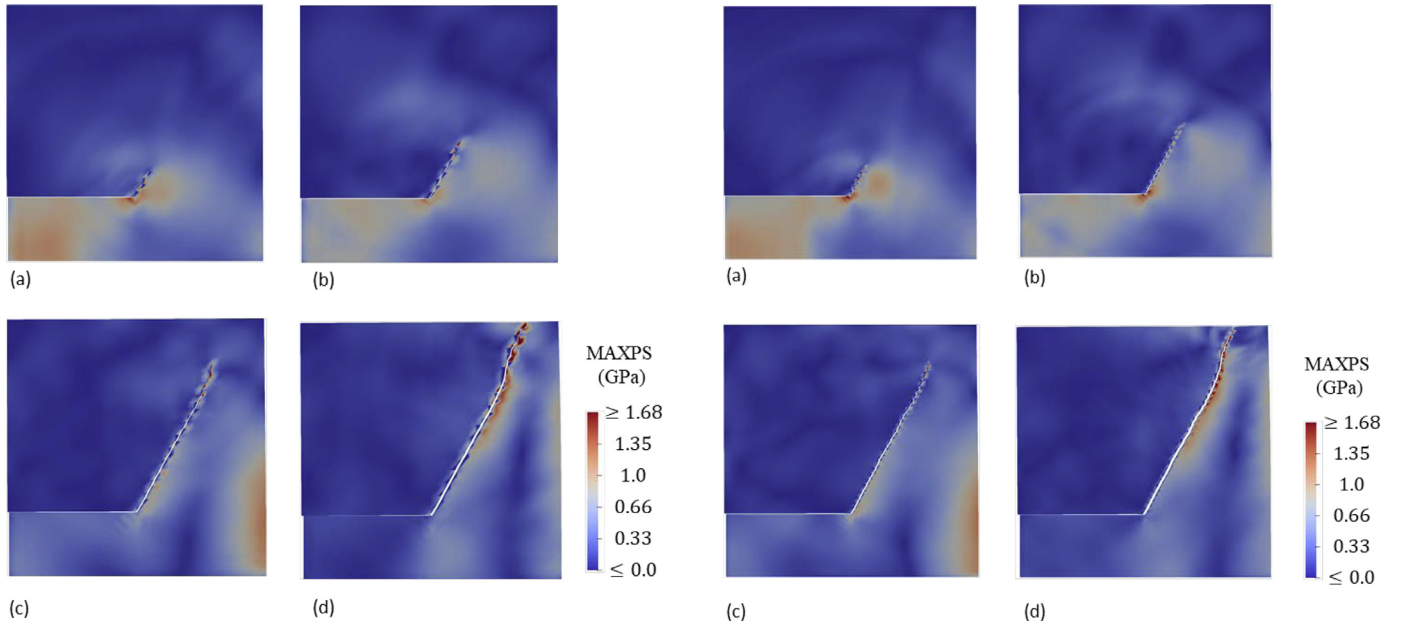

### 3. Governing equations, weak formulation and discretization

#### 3.1. Governing equations

Considering dynamic form of a two-dimensional problem, the governing equation is

**Fig. 9.** Experimental set-up and simulation model (a) Kalthoff experimental set-up for crack propagation under impulsive loading (b) Upper half of the plate used in the analysis.

**Fig. 10.** The computed crack paths on the  $40 \times 40$  deformed mesh with a maximum principle stress at different time steps: (a)  $t = 29.89 \mu s$ ; (b)  $t = 37.43 \mu s$ ; (c)  $t = 58.48 \mu s$ ; and (d)  $t = 81.28 \mu s$ .

**Fig. 11.** The computed crack paths on the  $80 \times 80$  deformed mesh with a maximum principle stress at different time steps: (a)  $t = 28.83 \mu s$ ; (b)  $t = 38.09 \mu s$ ; (c)  $t = 57.0 \mu s$ ; and (d)  $t = 79.98 \mu s$ .

$$\frac{\partial P_{ji}}{\partial X_j} + \rho_0 b_i - \rho_0 \ddot{u}_i = 0 \quad \text{in } \Omega_0 \quad (25)$$

where  $\mathbf{P}$  is the nominal stress tensor,  $\rho_0$  is the initial density and  $\mathbf{b}$  is the body force vector per unit mass. The boundary conditions are

$$\begin{aligned} u_i &= \bar{u}_i \quad \text{on } \Gamma_u^0 \\ [[u]]_j &= [[\bar{u}]]_j \quad \text{on } \Gamma_{uc}^0 \\ n_j^0 P_{ji} &= \bar{t}_i^0 \quad \text{on } \Gamma_t^0 \\ n_j^{0\pm} P_{ji}^{\pm} &= \tau_i^{0c} ([[u_i]]) \quad \text{on } \Gamma_c^0 \end{aligned} \quad (26)$$

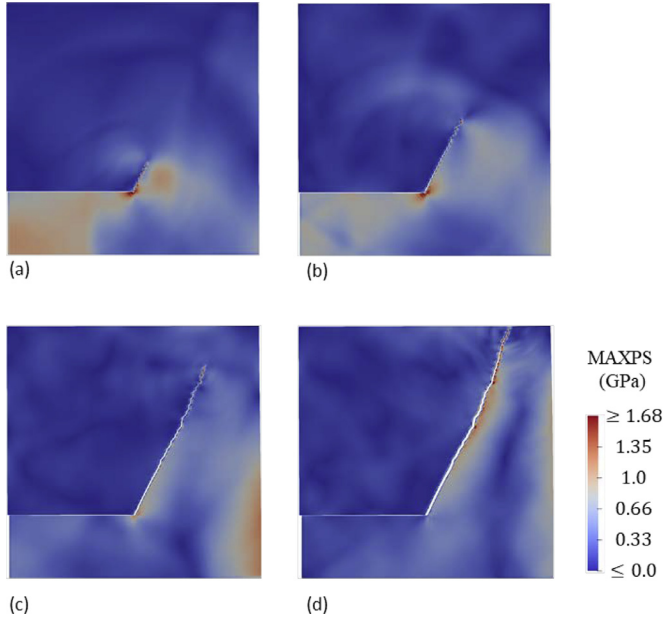

where  $\bar{\mathbf{u}}$  is the applied displacement on the Dirichlet boundary  $\Gamma_u^0$ ,  $[[\bar{\mathbf{u}}]]$  is the prescribed displacement jump on a set of non-nodal points  $\Gamma_{uc}^0$ ,  $\bar{\mathbf{t}}^0$  is the applied traction on the Neumann boundary  $\Gamma_t^0$  and  $\tau^{0c}$  is the

cohesive traction across the crack boundary  $\Gamma_c^0$ . Indicical notation is used for lower case indices. It must be stressed out that a crack tip can be simply modeled by imposing a homogenous boundary condition as

$$[[\mathbf{u}]]_j = 0 \quad \text{at cracktip} \quad (27)$$

### 3.2. Weak formulation

The admissible space for the trial and test functions is defined as follows:

**Fig. 12.** The computed crack paths on the  $120 \times 120$  deformed mesh with a maximum principle stress at different time steps: (a)  $t = 28.96 \mu\text{s}$ ; (b)  $t = 38.45 \mu\text{s}$ ; (c)  $t = 56.49 \mu\text{s}$ ; and (d)  $t = 77.4 \mu\text{s}$ .

$$\begin{aligned} \mathfrak{A} &= \{\mathbf{u} \mid \mathbf{u} \in C^0, \mathbf{u} = \bar{\mathbf{u}} \text{ on } \Gamma_u^0, [[\mathbf{u}]] = [[\bar{\mathbf{u}}]] \text{ on } \Gamma_{uc}^0, \\ &\mathbf{u} \text{ discontinuous on } \Gamma_c\} \\ \mathfrak{A}_0 &= \{\delta \mathbf{u} \mid \delta \mathbf{u} \in C^0, \delta \mathbf{u} = 0 \text{ on } \Gamma_u^0, \delta [[\mathbf{u}]] = 0 \text{ on } \Gamma_{uc}^0, \\ &\delta \mathbf{u} \text{ discontinuous on } \Gamma_c\} \end{aligned} \quad (28)$$

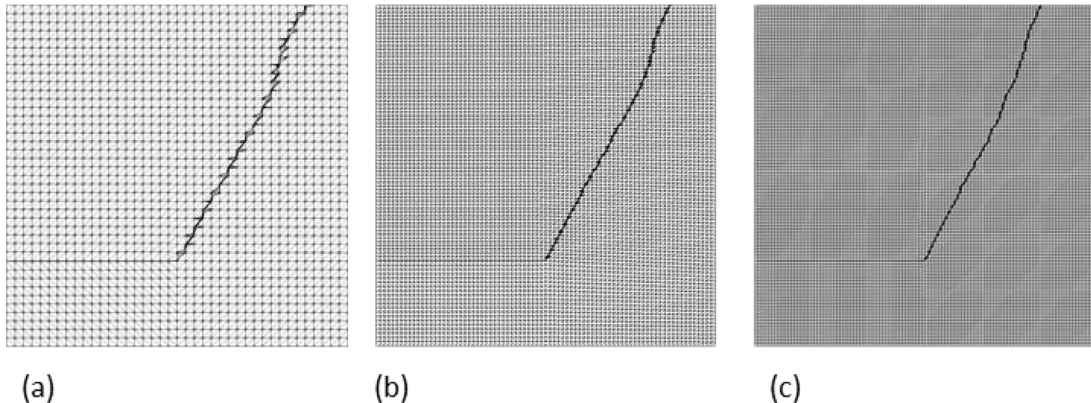

The weak form is expressed as an integral form of the momentum equation so that for  $\mathbf{u} \in \mathfrak{A}$  and  $\forall \delta \mathbf{u} \in \mathfrak{A}_0$

$$\delta W^{\text{kin}} = \delta W^{\text{ext}} - \delta W^{\text{int}} + \delta W^{\text{coh}} \quad (29)$$

where  $\delta W^{\text{kin}}$  is the kinetic work,  $\delta W^{\text{ext}}$  the external work,  $\delta W^{\text{int}}$  the internal work and  $\delta W^{\text{coh}}$  the cohesive work achieved by the cohesive traction on the crack surface. The Eq. (29) can be expanded as follows

$$\begin{aligned} \int_{\Omega_0} \delta \mathbf{u} \cdot \rho_0 \ddot{\mathbf{u}} d\Omega_0 &= \int_{\Omega_0} \delta \mathbf{u} \cdot \rho_0 \mathbf{b} d\Omega_0 + \int_{\Gamma_f^0} \delta \mathbf{u} \cdot \bar{\mathbf{f}}^0 d\Gamma_0 \\ &\quad - \int_{\Gamma_c} [[\delta \mathbf{u}]] \cdot \tau^c d\Gamma_0 - \int_{\Omega_0} \partial \mathbf{F}^T : \mathbf{P} d\Omega_0 \end{aligned} \quad (30)$$

where  $\mathbf{F}$  is the deformation gradient.

**Fig. 13.** Comparison of crack propagation trajectories at final simulation step using triangular linear elements (a)  $40 \times 40$  mesh; (b)  $80 \times 80$  mesh; and (c)  $120 \times 120$  mesh.

**Table 1**

Crack propagation angles and timing data for the Kalthoff's experiment simulations.

Mesh	Angles (°)		Time (μs)	
	Initial	Overall	Propagation	Simulation
$40 \times 40$	60.16	62.45	25.61	81.28
$80 \times 80$	61.87	64.74	22.59	79.98
$120 \times 120$	63.34	67.1	19.79	77.4

### 3.3. Discretization

The finite element discretization relates each of the virtual work terms in Eq. (29) to a discretized nodal force as follows:

$$\mathbf{f}^{\text{kin}} = \mathbf{f}^{\text{ext}} - \mathbf{f}^{\text{int}} + \mathbf{f}^{\text{coh}} \quad (31)$$

where  $\mathbf{f}^{\text{kin}}$ ,  $\mathbf{f}^{\text{ext}}$ ,  $\mathbf{f}^{\text{int}}$  and  $\mathbf{f}^{\text{coh}}$  are the kinematic, external, internal and cohesive forces, respectively. These forces are constructed by assembling the local element force vectors:

$$\mathbf{f}_e^{\text{kin}} = \int_{\Omega^e} \rho \mathbf{N}_e^{\text{gT}} \mathbf{N}_e^{\text{g}} d\Omega^e \ddot{\mathbf{d}}_e^{\text{g}} \quad (32)$$

$$\mathbf{f}_e^{\text{ext}} = \int_{\Omega^e} \rho \mathbf{N}_e^{\text{T}} \mathbf{b}_e d\Omega^e + \int_{\Gamma_f^e} \mathbf{N}_e^{\text{T}} \bar{\mathbf{f}}_t^e d\Gamma_t^e \quad (33)$$

$$\mathbf{f}_e^{\text{int}} = \int_{\Omega^e} \mathbf{B}_e^{\text{gT}} \mathbf{S}_e^{\text{g}} d\Omega^e \quad (34)$$

$$\mathbf{f}_e^{\text{coh}} = - \int_{\Gamma_c^e} [[\Psi]]^T \tau^c \mathbf{n} d\Gamma_c^e \quad (35)$$

Here the superscript  $e$  is the element number,  $\mathbf{S}$  is the second Piola–Kirchhoff stress in Voigt form,  $\mathbf{d}_e^{\text{g}} = [\mathbf{u}_e, [[\mathbf{u}]]_f]$  is the generalized nodal coefficient vector consisting of nodal displacements and enrichment variables,  $\mathbf{N}_e^{\text{g}}$  is the union of regular shape functions and enrichment functions and  $\mathbf{B}_e^{\text{g}}$  is generalized strain-displacement matrix. The  $\mathbf{N}_e^{\text{g}}$  matrix is given by

$$\mathbf{N}_e^{\text{g}} = [\mathbf{N}_e^0, \Psi_f] \quad (36)$$

The  $\mathbf{B}_e^{\text{g}}$  is also given by

$$\mathbf{B}_e^{\text{g}} = [\mathbf{B}_e^0, \mathbf{B}_e^c] \quad (37)$$

where

$$\mathbf{B}_I^0 = \begin{bmatrix} N_{I,X} x_{,X} & N_{I,X} y_{,X} \\ N_{I,Y} x_{,Y} & N_{I,Y} y_{,Y} \\ N_{I,X} x_{,Y} + N_{I,Y} x_{,X} & N_{I,X} y_{,Y} + N_{I,Y} y_{,X} \end{bmatrix} \quad (38)$$

$$\mathbf{B}_I^c = \begin{bmatrix} \Psi_{I,XX} & \Psi_{I,XY} \\ \Psi_{I,XY} & \Psi_{I,YY} \\ \Psi_{I,XY} + \Psi_{I,YX} & \Psi_{I,XY} + \Psi_{I,YX} \end{bmatrix} \quad (39)$$

where  $(.)_i$  indicates the partial derivative along the  $i$ th coordinate direction.

### 3.4. Time integration scheme and critical time step

In this study, the explicit time integration with the consistent mass matrix was used. The explicit time integration is conditionally stable, i.e. it is stable when

$$\Delta t < \Delta t_c = \frac{2}{\omega_{\max}} \quad (40)$$

By studying the frequencies  $\omega_i$  of the one-dimensional discrete system  $\omega_i^2 \mathbf{M} \mathbf{d}_i = \mathbf{K} \mathbf{d}_i$ , the variation of the critical time step according to the normalized location of the crack was pre-determined to ensure the stability in the explicit time integrator. Fig. 7 compares the normalized critical time step size of the non-nodal XFEM to the standard XFEM.

For the standard XFEM, the peak value of the critical time step size occurs when the crack is at element midspan in contrast to the non-nodal XFEM for which the minimum of the critical time step occurs at the middle. This implies that the non-nodal XFEM is more efficient than

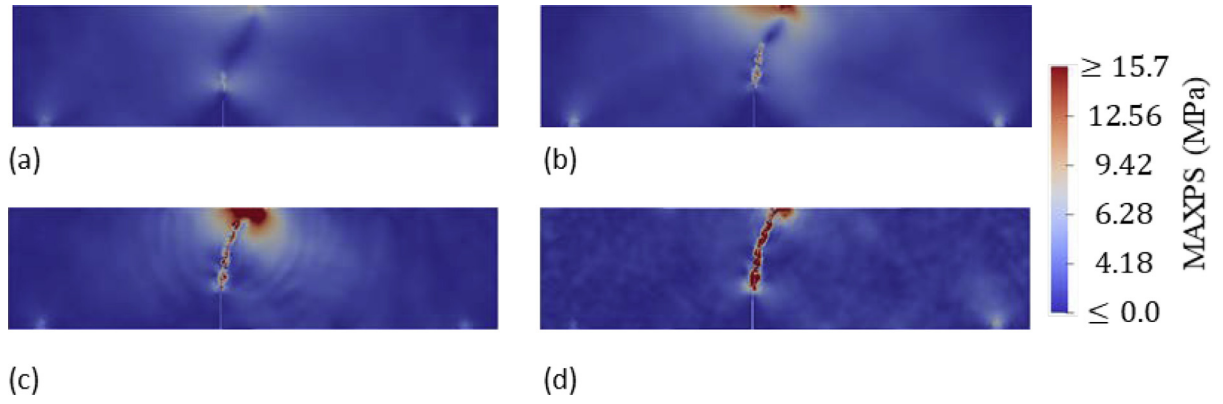

Fig. 23. The crack evolution for the medium mesh: (a)  $t = 370.43 \mu s$ ; (b)  $t = 531.64 \mu s$ ; (c)  $t = 607.73 \mu s$ ; and (d)  $t = 742 \mu s$ .

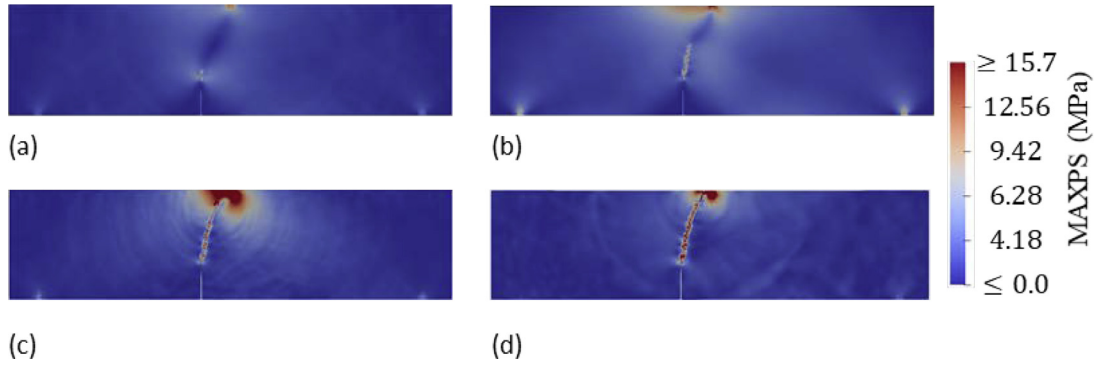

Fig. 24. The crack evolution for the fine mesh: (a)  $t = 346.43 \mu s$ ; (b)  $t = 513 \mu s$ ; (c)  $t = 616 \mu s$ ; and (d)  $t = 688 \mu s$ .

Table 2

Crack propagation angles and timing data for the Guo's experiment simulations.

Mesh	Angles (°)		Propagation time $\mu s$
	Initial ( $\theta_1$ )	Final ( $\theta_2$ )	
Coarse mesh	9.5	11.85	360
Medium mesh	9.0	13.1	319
Fine mesh	10.0	14.0	305

the standard XFEM. Furthermore, for standard XFEM, the critical time step drops linearly to zero as the crack location approaches to the element nodes which leads to numerical difficulties in explicit time integration schemes. However, the critical time steps of the non-nodal XFEM are approached to those obtained for a regular finite element

with a consistent mass matrix, when the discontinuity approaches to element nodes. Therefore, the proposed method can be directly used for arbitrary cracks modeling.

#### 4. Cohesive law

The cohesive model is applied to the damage evolution created by the crack. In a cohesive model, a surface traction determined by a cohesive law is applied onto the crack surfaces  $\Gamma_c$  such that the energy dissipated due to the crack evolution matches the critical fracture energy. In this study, we considered only the normal component of the traction. The normal displacement jump  $\delta_N$  is defined by

$$\delta_N = \mathbf{n} \cdot [[\mathbf{u}]] = \mathbf{n} \cdot \sum_{J \in \delta_{en}} [[\Psi]]_J [[\mathbf{u}]]_J \quad (41)$$

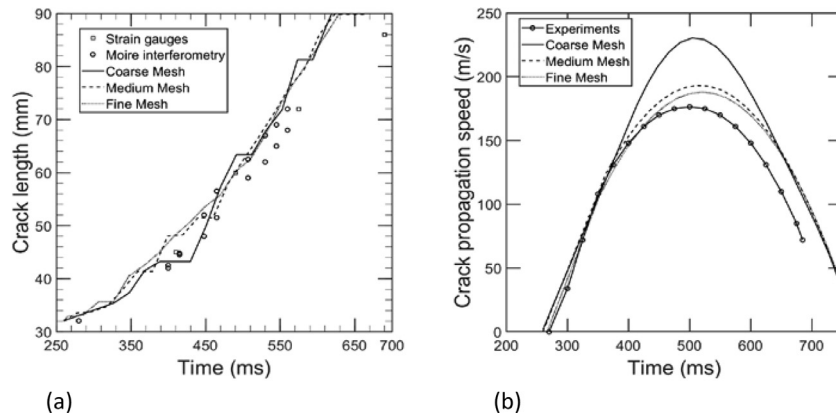

Fig. 25. Crack length history and crack speeds obtained in numerical simulations for different meshes compared to the Guo's experiment: (a) the crack length histories; and (b) the crack speeds.

In general, the cohesive traction can be computed incrementally with radial return algorithm as follows:

$$\begin{aligned}
 &\text{input: } \delta_N \\
 &\delta_N^0 = \delta_N^{\text{prev}} \\
 &\tau_N^0 = \tau_N^{\text{prev}} \\
 &E^0 = E^{\text{prev}} \\
 &\text{for } i = 1 \text{ to } N \\
 &\quad \delta_N^i = \delta_N^{i-1} + \frac{i \times \delta_N}{N} \\
 &\quad \text{if } \delta_N^i > 0 \\
 &\quad \quad \tau_N^{\text{trial}} = \tau_N^{i-1} + E^{i-1}(\delta_N^i - \delta_N^{i-1}) \\
 &\quad \quad \text{if } \tau_N^{\text{trial}} > f(\delta_N^i) \\
 &\quad \quad \quad \tau_N^i = f(\delta_N^i) \\
 &\quad \quad \quad E^i = \tau_N^i / \delta_N^i \\
 &\text{return } \tau_N^i
 \end{aligned} \quad (42)$$

where  $\delta_N$  and  $\delta_N^i$  are the normal displacement and incremental displacement, respectively. In the radial return algorithm, the loop invariant is  $E_N = \tau_N^i / \delta_N^i$  while  $\delta_N^i$  and  $\tau_N^i$  are underneath the traction law illustrated in Fig. 8.

For the linear cohesive model, we have

$$\delta_{\max} = \frac{2G_F}{\tau_{\max}} \quad (43)$$

In this study, normal cohesive traction is considered only since mode I failure is a dominant failure mode of the subsequently described failure problems.

## 5. Numerical examples

In this section, we examine the performance of non-nodal XFEM through three benchmark problems for which the experimental results are available. We compare the method with conventional XFEM to effectively demonstrate merits and demerits of the method. We now define notable features that will be used in the numerical simulations that follow. All simulations were modeled with linear triangular elements in plane strain and the thickness was chosen to be unity. The central difference method for time integration is used with a Courant number of 0.1. To advance the crack, the maximum tensile stress computed at the crack tip was considered as fracture criterion along with an element-by-element propagation of the crack. For the crack propagation direction, we used the normal to the maximum tensile stress direction. To eliminate the awkward oscillations in stress computation, once an element failed, a nodal smoothing is performed for the stresses around the crack tip.

### 5.1. Edge-cracked plate under impulsive loading

The first numerical example deals with an experiment carried out by Kalthoff and Winkler [28] in which a plate with two initial edge notches impacted by a projectile. Numerical results for this problem have been given by Belytschko et al. [29] and Song et al. [30]. Kalthoff observed two different failure modes by modifying the projectile speed  $V_0$ ; at lower impact velocities, a brittle fracture with a crack propagation at an angle of about  $70^\circ$  was observed while at higher impact velocities, a strain localization, i.e. a shear band was observed at a negative angle of about  $-10^\circ$  with respect to the notch. In this work, we consider only the brittle fracture mode.

Due to twofold symmetry, only the upper half of the plate is modeled. A schematic description of the original problem and the upper part to be solved are shown in Fig. 9(a) and (b), respectively. The symmetry condition  $u_y = 0$  was imposed at the bottom edge of the model. The initial velocity is applied as a step function on the left edge on  $0 \leq y \leq 25$  mm. Assuming that the projectile and the plate have identical elastic impedance, an applied velocity of 16.5 m/s is chosen, which

is one-half of the projectile speed in the experiment.

The plate is a maraging steel 18Ni1900 with the following material parameters:  $E = 190$  GPa,  $\rho = 8000$  kg/m<sup>3</sup> and  $\nu = 0.3$ ; so, the Rayleigh wave speed is roughly  $c_R = 2800$  m/s. The critical stress intensity factor is taken as  $K_{Ic} = 68$  MPa $\sqrt{\text{m}}$  which leads to a fracture energy  $G_F = 2.217 \times 10^4$  J/m<sup>2</sup>. We used a linear cohesive crack model with a tensile strength of  $\tau_{\max} = 844$  MPa which corresponds to a critical crack opening displacement  $\delta_{\max} = 5.245 \times 10^{-5}$  m. To observe the mesh sensitivity, we have analyzed the model with three different uniform meshes: a  $40 \times 40$  coarse mesh, a  $80 \times 80$  medium mesh and a  $120 \times 120$  fine mesh. The crack evolutions for each mesh are shown in Figs. 10–12.

The finite element meshes and their crack growth trajectories are shown in Fig. 13. The simulations terminated when the crack tip passed the upper boundary; all simulations yielded quite similar crack propagation trajectories which agree quite well with those obtained by the conventional XFEM [29,30]. The numerical results for each simulation are listed in Table 1. The data in Table 1 show that the crack begins to propagate at earlier times with mesh refinement, which leads to a shorter simulation time. For all simulations, the crack first grows primarily along an initial angle, then near the end of the simulation moves a little bit upward.

The initial and the average overall crack propagation angles are increasing with mesh refinement; the overall angle is approaching to the experimental value with mesh refinement as the overall angle of  $67.1^\circ$  in fine mesh compares well with the experimental value of  $70^\circ$ .

The crack tip propagation speeds for  $40 \times 40$  and  $80 \times 80$  meshes computed by both the proposed method and the conventional XFEM are shown in Fig. 14. As it is demonstrated in Fig. 14(a), for both meshes, the proposed method yields very similar crack speeds. When the crack begins to propagate, its speed oscillates around 2000 m/s and after around  $50 \mu\text{s}$ , the crack speed slowly decreases up to the end of the simulation. However, for the conventional XFEM, the crack speeds for the fine mesh are obtained significantly higher than for the coarse mesh. These results confirm the previous results in Reference [29]. Therefore, we can conclude that the proposed method demonstrates less mesh dependency than the conventional XFEM.

### 5.2. Crack pattern in three-point bending specimens with variable offset notch

Experiments concerning mixed mode dynamic crack propagation in three point bending specimens subjected to impact loading were conducted by John and Shah [31]. The numerical solutions for this example can be found in [30,32–35]. The experimental setup is shown in Fig. 15(a). To induce mixed-mode condition, a notch was located at a variable offset from the midspan. In these series of experiments, the crack patterns and crack initiation angles of specimens are examined for the offset notch at various locations. Finally, for several experiments, three crack propagation patterns were reported depending on the location of the notch which can be described by a normalized parameter  $\gamma$ .

$$\gamma = \frac{d_{\text{notch}}}{L/2} \quad (44)$$

where  $d_{\text{notch}}$  denotes the distance between the midspan and the notch, and  $L$  is the distance between the supports. A transition point was observed in the notch location  $\gamma_b$  where failure changes from a crack growth at the offset notch ( $\gamma < \gamma_b$ ) to a crack growth at the midspan ( $\gamma > \gamma_b$ ). For a narrow transition region where offset parameter is close to  $\gamma_b$ , both notch and midspan cracks initiate and propagate. The experimentally obtained value of  $\gamma_b$  is 0.77.

Material properties are density  $\rho = 2400$  kg/m<sup>3</sup>, Young's modulus  $E = 31.37$  GPa, Poisson's ratio  $\nu = 0.2$  and tensile strength of  $\tau_{\max} = 10.45$  MPa. A linear cohesive crack model was used with a fracture energy of  $G_F = 19.58$  J/m<sup>2</sup> and its corresponding critical crack

opening displacement  $\delta_{\max} = 3.75 \times 10^{-6} \text{m}$ . To model the rubber pad between the beam and impact hammer, the velocity boundary condition at the loading point is applied as a ramp function defined by

$$V(t) = \begin{cases} V_0 t/t_{\text{ramp}} & t \leq t_{\text{ramp}} \\ V_0 & t \geq t_{\text{ramp}} \end{cases} \quad (45)$$

where  $V_0 = 0.06 \text{m/s}$  and  $t_{\text{ramp}} = 196 \mu\text{s}$ . The imposed velocity was calibrated to result in a strain rate of  $0.3 \text{s}^{-1}$  at the midspan which was reported in the experiments (see Reference [32]).

Numerical simulations with three different meshes were carried out: a coarse mesh of around 1000 elements, a medium mesh of around 4000 elements and a fine mesh of around 15,000 elements. The finite element meshes are shown in Fig. 15(b)–(d). The numerical experiments were conducted with various offset parameters to capture observed failure patterns. The numerical simulations show that the initial notch location for the transition stage approaches to the experimentally determined value with mesh refinement. As shown in Fig. 15(b)–(d), the  $\gamma_t$  for the fine mesh was obtained as 0.78, which agrees quite well with experimental result of 0.77. The crack propagation paths for each mesh are shown in Figs. 16–18.

The observed three numerical crack patterns for the fine mesh are shown in Fig. 19. As it is shown for  $\gamma = 0.75$  the crack propagates only from the offset notch with an angle of  $59^\circ$  which is very close to the experimental value of  $60^\circ$ . At the final stage of crack growth, the crack rotates a little bit toward the loading point which was also reported in experiments. For  $\gamma = 0.78$  where the offset notch is in transition zone, two cracks are initiated both at the midspan and the notch and propagate simultaneously, but the final failure occurs at the midspan. Finally, for  $\gamma = 0.785$ , only one main crack is initiated at the midspan and propagates toward the loading point.

### 5.3. Crack extension and velocity in three-point bending specimens

In order to compare the crack speeds of the proposed method with those reported in experiments of three-point-bend specimens, we examined an experiment reported by Guo et al. [36]. This experiment has been also numerically modeled by Ruiz et al. [33] in three dimensions. The experimental set-up is shown in Fig. 20(a). The offset notch is located at 25.4 mm from midspan and extended by approximately 13 mm.

The material used in the simulation has the following properties: density  $\rho = 2400 \text{kg/m}^3$ , Young's modulus  $\rho = 32.3 \text{GPa}$  and Poisson's ratio  $\nu = 0.2$ . Since the load-line displacements were reported in experiments, the impact loading can be applied as a prescribed displacement (for more details, refer to References [33,36]). The dynamic tensile strength of 7.75 MPa (2.5 times of tensile strength) is taken as the maximum tensile stress. A linear cohesive crack model was used with fracture energy of  $G_F = 120 \text{J/m}^2$ . To examine the mesh sensitivity, three different triangular meshes were used in the numerical simulations as illustrated in Fig. 20(b)–(d).

Fig. 21(a) shows the averaged crack path obtained in experiments. The experiments show that, the crack first grows primarily along an initial angle  $\theta_1$  measured from vertical line, then after passing half width of the beam, it rotates  $\theta_2$  degrees with respect to initial angle toward the loading point. As shown in Fig. 21(a), the experimentally computed values of  $\theta_1$  and  $\theta_2$  are  $10^\circ$  and  $16^\circ$ , respectively.

The crack patterns and the crack evolutions for three different meshes are shown in Fig. 21(b)–(d) and Figs. 22–24, respectively. The simulation results are listed in Table 2. The outcomes show that the crack starts propagating in an earlier time with mesh refinement. All simulations have similar crack propagation paths. In these simulations, the crack propagation angles  $\theta_1$  and  $\theta_2$  are in excellent agreement with the experimentally observed value of  $10^\circ$  and  $16^\circ$ , respectively.

The crack length histories and speeds for different meshes are illustrated in Fig. 25. As it can be seen, the crack speed for the coarse mesh was obtained substantially higher than the experimental speed. For the

medium and fine meshes, the crack speeds compare well with observed values. This example demonstrates that for the proposed method, a fine mesh may improve the accuracy of the results.

## 6. Conclusions

A new XFEM-based method, which we referred as a non-nodal XFEM, within an explicit time integration scheme has been developed for modeling strong discontinuities in two-dimensional planes. In this method, the discontinuities across an interface are assigned to a set of non-nodal points on the interface. The enrichment variables are defined as *physically-based* quantities and the enrichment functions are defined to be completely vanished outside the element domain. In the proposed method, a local partition of unity is not constructed that excludes the element nodes from the construction of enrichment functions. This feature dramatically simplifies the implementation of the non-nodal

XFEM, unlike the conventional XFEM and its variants including the phantom node method [30,37].

It was demonstrated through three examples that the proposed method can be successfully used in dynamic crack modeling. In the Kalthoff's experiment, this method resulted very similar crack patterns independent of the mesh size. Furthermore, the crack tip speed discrepancy was negligible with mesh refinement, in contrast to conventional XFEM. For mixed-mode crack propagation in three-point-bend specimens, we analyzed the experiments conducted by John and Shah [31] and Guo et al. [36]. In these sequence of numerical experiments, the overall crack propagation paths agreed quite well with those values determined in the experiments. However, in some cases, the crack propagation angles and the crack tip speeds approached to the experiments by mesh refinement. The numerical examples demonstrate that the method can be used for modeling strong discontinuities with the added advantage of excluding the element nodes from extended interpolation.

Finally, we would like to point out that the proposed methodology may be used to model discontinuities in derivatives of a function.
