Reassessing the Capacities of Entertainment Structures in the Roman Empire

J.W. HANSON AND S.G. ORTMAN

Supplementary Appendix at www.ajaonline.org

In recent years, scholars have become increasingly skeptical of the idea that there is any relationship between the capacities of entertainment structures such as theaters and amphitheaters and the populations of Graeco-Roman cities. In this article, we begin by offering a model of information percolation in cities grounded in settlement scaling theory. We then show that there is a systematic relationship between the capacities of both theaters and amphitheaters and the populations of cities in the Roman empire, but this relationship is far from linear, indicating that a decreasing fraction of the population attended events in entertainment structures. In addition, although there is a great deal of variation in the extent to which sites conform to the underlying relationships, there is a relationship between the sizes of these deviations and the overall standing of sites as reflected in their civic statuses. Collecting similar measures for other relationships might be a useful way of characterizing sites and indicates a fruitful avenue for future research.¹

INTRODUCTION

Despite initial enthusiasm about using the numbers of seats in entertainment structures, such as theaters, amphitheaters, and (less often) circuses, as a proxy for the number of residents in Graeco-Roman cities, there has been increasing skepticism over the past 50 years about whether there is any relationship between the capacities of these structures and the populations of the sites in which they are found.² This skepticism revolves around two main issues. The first is the association of entertainment structures with competition among and between elites for public recognition.³ This is often discussed in the context of the dependence of Graeco-Roman cities on civic munificence—that is, on a cycle of activities that enabled elites to generate public approval by contributing their wealth to the public good through, for example, the construction of public buildings and the provision of the lavish spectacles that took place in and around them.⁴ An entertainment structure

³Laurence et al. 2011.

might be sized to display the donor’s wealth and status rather than scaled to civic needs. This munificence is demonstrated both by epigraphic material, which highlights the importance of offering entertainment in the careers of the elite, and by the actual seating arrangements of theaters and amphitheaters, where the best seats were often reserved for officials, dignitaries, and other important visitors.\(^5\) The second issue is the likelihood that at least some of the spectators who filled these structures came from elsewhere.\(^6\) Such a situation is famously described by Tacitus, who reports a riot between the residents of Pompeii and visitors from Nuceria in 59 CE at a gladiatorial show; this riot eventually resulted in a senatorial ban of such events for 10 years, but similar incidents are known to have occurred elsewhere.\(^7\) Additional support for this interpretation comes from nearly 100 notices on the walls of Pompeii (the so-called *edicta munera*), which advertise a regular calendar of events, presumably reflecting the efforts of their sponsors to attract the largest crowds possible.\(^8\) The most striking aspect of these notices is that, although most relate to events in Pompeii, some refer to events in neighboring settlements (such as Herculanenum, Nuceria, and Nola) and slightly more distant places (such as Puteoli, Cuma, Capua, Caes, and Forum Popili) (fig. 1, table 1). As a result, it is not clear whether the capacities of entertainment structures reflect competition among elites (and therefore the wealth and status of the site), the numbers of spectators who could have come from elsewhere (and therefore the sizes of the catchments and overall social and economic influence of sites), or both. It is for these reasons that scholars have had difficulties using the capacities of entertainment structures to estimate the populations of ancient cities.

We believe the time is ripe to reassess the links between the capacities of entertainment structures and urban populations for two reasons. First, there is increasing evidence for systematic relationships between the sizes of settlements and their infrastructure in both ancient and modern contexts.\(^9\) For example, recent work has demonstrated consistent relationships between the populations of Graeco-Roman cities and the dimensions of mixing spaces, such as forums and agoras, and street networks.\(^10\) An important question is, therefore, whether such relationships can also be detected for entertainment structures. Second, an important consequence of recent work has been the development of independent estimates of the populations of sites, based on the sizes of their inhabited areas and on their residential densities.\(^11\) Although these figures are approximate, they do nonetheless allow one to look at the overall relationships between the sizes of sites and the capacities of entertainment structures for the first time.

Here, we combine existing measurements of the capacities of entertainment structures with recent population estimates to examine the relationships between them, allowing us to shed new light on the functions of these structures. We also examine the extent to which deviations of individual cities from the average relationship between population and structure capacity reflect local differences among sites, such as variation in the wealth and status of sites or the populations of neighboring settlements.

This article is grounded in an approach that has come to be known as settlement scaling theory.\(^12\) This approach views human settlements as built

---

environments that facilitate interactions among individuals in space and time and so lead to systematic relationships between the populations of settlements and various elements of their built environments. We use this approach to investigate the extent to which the capacities of entertainment structures are related to the populations of cities and to assess the degree to which other factors might have influenced these capacities. We begin by offering an abstract model for how entertainment structures in Graeco-Roman cities might have functioned, which is based on recent insights from complex systems concerning the percolation of information through social networks.\textsuperscript{13} We then describe how we have arrived at estimates of the numbers of residents in settlements and the numbers of seats in entertainment structures before discussing their relationship.

We show that there is indeed a systematic relationship between the populations of sites and the capacities of both theaters and amphitheaters. This relationship is not linear, however, meaning that the sizes of sites tend to grow much faster than the capacities of entertainment structures. On average, a smaller fraction of urban residents would have been able to attend events in entertainment structures in larger cities than was the case in smaller cities. A striking feature of our results is that the data for individual cities can deviate substantially from the overall average relationship (i.e., they can exhibit large residuals from the best-fit line, which is the plotted line that best describes the relationship between the capacities of entertainment structures and the populations of cities). We therefore investigate whether some of this variation can be accounted for using other properties of individual sites. Although our results are only preliminary, they suggest that deviations from the average relationship are correlated with civic status. These deviations indicate that the more important sites were more likely to have had a larger theater or amphitheater than we would expect based only on their size. Additional scale-adjusted urban indicators of this kind might be useful for a variety of purposes when the data are of sufficient quality.

**INFORMATION FLOW IN ANCIENT CITIES**

There is now a wide range of scholarship that highlights the importance of information percolation for the development of human settlements and regards the generation of shared experiences and knowledge through collective events as a key dimension of social cohesion.\textsuperscript{14} In this context, although most ancient cities were too large to have relied on continuous face-to-face interaction to maintain social cohesion, they were still small enough that they would not have needed to rely on the kinds of broadcast media that are used for this purpose in the modern world.\textsuperscript{15} As a result, we would expect one of the social technologies developed by ancient societies to facilitate social cohesion to have been collective events that involved a sufficiently large fraction of the community that any information conveyed through the event could percolate, or be readily disseminated, through the rest of the social network.\textsuperscript{16}

In this section, we provide a formal model for how the experience of attending an event, and any other information that was conveyed by that event, could have been disseminated from an initial group of witnesses to the rest of the community.

Our model is based on the idea that information is one of the most fundamental quantities that flows through social networks. The percolation of information through a social network is determined by a combination of the number of people who receive such visual or auditory information and their ability to pass on this information to others. A model for the percolation of information through a social network

\\[ \text{Percentage of community reached} = 1 - e^{-\mu N} \]

Where $\mu$ is the percolation rate and $N$ is the number of people who receive the information.

\textsuperscript{13}Bettencourt 2014; Schläpfer et al. 2014.

\textsuperscript{14}See Smith 2018 for an introduction to some of these ideas.

\textsuperscript{15}Zuiderhoek 2016, 97.

\textsuperscript{16}See Canuto and Yaeger 2000 for discussion of these ideas in other contexts.
can therefore be based on three simple variables: the number of people who originally witnessed an event, the average number of social contacts that each individual has (known as the average degree), and the number of times we would expect the news to be transmitted from individual to individual (known as the path length). It is then a simple enough task to put this into mathematical form, beginning with an initial number of witnesses and considering how many average social contacts would be necessary and how many times information would have to be transmitted for the associated social information to spread throughout the community. It is important to point out that we would not necessarily expect these social networks to be confined to the immediate residents of cities, since they could also include anyone who regularly interacted with others in the context of the built environment, in keeping with how modern settlements are treated.

A variety of evidence supports the view that the average social connectivity of individuals increases proportionately to settlement population density and that density increases with settlement population. Given this, a decreasing fraction of the urban population will need to be exposed directly to a message for it to be disseminated to the entire population in a given number of steps. The size of this necessary fraction can be computed by considering the total number of people who receive the message at a given number of degrees of separation from the original witnesses. This is given by the final term of the geometric series:

\[ N_r = N_w k_w^{-h}, \]  

where \( N_r \) is the total number of people who receive the message, \( N_w \) is the number of witnesses, \( k_w \) is the average number of social contacts of each witness (i.e., the average degree), and \( h \) is the average path length, or the number of social intermediaries, through which the news travels (i.e., the network distance).

Next, we can represent the fraction of inhabitants of a city of size \( N \) who were eyewitnesses to events in entertainment structures as \( N_w = N^\beta \), with \( \beta < 1 \), and the average connections of the witnesses as \( k_w = k_0 N^\delta \), where \( k_0 \) is the baseline number of social contacts, \( N \) is the population, and \( \delta \) is the average number of social contacts that each person has, based on recent theoretical and empirical work. This allows us to specify the relationship between the numbers of people who received a message and the numbers of eyewitnesses by substituting these relationships into equation (1), as follows:

\[ N_r = k_0 N^{\beta + h\delta}. \]  

If we further assume that every individual eventually receives the message, the value of \( k_0 \) and the exponent \( \beta + h\delta \) both become equal to one, leading to \( N_r = N \).

In addition, we would expect the average connectivity between individuals to increase proportionately with the population density, such that the value of \( \delta \) can be determined by specifying how the densities of settlements change with the size of their inhabited areas. Based on earlier work, we can write \( A = a N^{1-\delta} \), where \( A \) is the inhabited area of a site and \( a \) is a baseline density, which can be rearranged to solve for population \( N \) as follows:

\[ N = (1/a)^{1/1-\delta} A^{1/1-\delta}. \]  

We can then solve for the population density \( D \) as follows:

\[ D = N/A = (1/a)^{1/1-\delta} A^{-1/1-\delta}. \]  

As we have shown elsewhere, since the value of \( \delta \) is about 1/3 for Graeco-Roman cities, the average social connectivity of individuals should increase with the urban population raised to the \( \delta = 1/3 \) power. As a result, if residents sought to create built environments in which everyone could receive the information conveyed at public events secondhand (i.e., directly from eyewitnesses, such that \( h = 1 \)), we would expect the capacities of entertainment structures to increase with population raised to the \( \beta = 2/3 \) power. But, if the information could be obtained thirdhand (\( h \to 3 \)), the exponent \( \beta \to 0 \), meaning that the fraction of the population exposed to the information, can approach a constant that does not change with city size. However, it is also important to recognize that information degrades with each link in the chain of transmission. This implies that the quality of the information conveyed will also degrade with \( h \). We suggest that thirdhand accounts represent the practical limit for conveying the details of a specific

---

19 Hanson and Ortman 2017.
20 Hanson and Ortman 2017.
event to others with sufficient fidelity to be of much use. Thus, we consider $h = 2$ to be an upper limit.

Although these equations might initially seem quite daunting, they simply propose that the flow of social information within a settlement is set by the number of eyewitnesses, the number of people each person regularly interacts with, and the number of times a piece of information is transmitted from person to person. In other words, the smaller the initial number of eyewitnesses, the larger the number of people through whom the information has to pass if the information is to reach the entire settlement. This model allows us to imagine several scenarios for how many people would have to experience an event, how many people they would have to tell about it, how many times the information would have to be repeated for the news to spread throughout the community, and how these factors would have changed as cities increased in size. More specifically, these models suggest that we would expect there to be a linear relationship between the capacities of entertainment structures and the sizes of sites if everyone was expected to witness an event (i.e., with a slope, $\beta$, of 1), but an increasing sublinear relationship (i.e., for the capacities of entertainment structures to increase at a slower rate than the size of the sites) if some of the community heard about the event secondhand ($\beta = 2/3$) or even thirdhand ($\beta = 1/3$), reaching a practical limit after that ($\beta = 0$) (table 2).

At this stage, we should add a few comments on what we mean by social information. In the context of the entertainment structures discussed in this article, we would expect most of the information that was shared by spectators to have been about the events staged in these structures, including the quality of the performances, the results of contests, audience reactions, who participated in or sponsored the events, which important people attended, the content of announcements, and any interpretations of their sociopolitical significance. It should be acknowledged, though, that the architecture of theaters and amphitheaters conveyed messages in its own right and that these structures were also prominent locations for setting up inscriptions, writing graffiti, or sharing gossip. Here, we only focus on the former category of social information, that related to the events themselves.

It is important to stress that our model does not require that people were aware of the formal relationships among community size, social connectivity, and information that we have specified above. We do, however, suggest that architects had a shared sense of the sociopolitical potential of theaters and amphitheaters and made a mental calculation of how large they needed to be to meet the perceived needs of the local community. Although we would not expect architects to have designed these structures for the express purpose of fostering social cohesion, it is widely accepted that both theaters and amphitheaters were designed to reinforce elite authority through displays of generosity and to appease the masses, as is reflected in the persistent use of the phrase “bread and circuses” to refer to the generation of public approval through diversions. It is therefore reasonable to view entertainment structures as having had an important role in fostering social cohesion.

We also stress that our model merely specifies the average relationship between entertainment structures and urban populations, as there are additional factors contingent upon local geographical or historical conditions that also influenced entertainment structure capacities in any given city. Thus, one can think of this model as providing a means of controlling for the effects of scale with regard to the social function of entertainment structures. When this is done, the degree to which the data for a given city deviates from the average relationship (the deviation is known in regression analysis as the residual) becomes a scale-adjusted urban indicator (i.e., an indication of how much a city deviates from the overall relationship, after taking its scale into account) that can be analyzed further to elucidate these additional factors.\footnote{Bettencourt et al. 2010.}

Finally, it should also be noted that this framework is dependent, at least in principle, on there being a correspondence between the capacities of entertainment structures and the sizes of sites at a given moment in time. Although most entertainment structures were probably built in response to urban growth, there were doubtless examples that fell short of or overcompensated for changing needs. As a result, there will inevitably be some mismatch between the capacities of entertainment structures and the populations of settlements. The best way to overcome these issues is to incorporate as many cases as possible into the analysis on the grounds that these errors will cancel one another out on average. Having said this, we would not expect these issues to affect the results very much, because we
would expect to observe these errors in the deviations away from the underlying relationship, rather than in the overall nature of the relationship itself (since there is an equal chance of using evidence that is either too early or too late). These deviations should also be relatively minor, because we would not expect that sites would have grown quickly enough to make much difference to the results.

In our analysis, we use the database of cities created by Hanson in his study of the Roman world in the Imperial period.\textsuperscript{22} To define cities, Hanson concentrated on sites that likely engaged in secondary and tertiary activities (manufacture, services, and trade) rather than primary ones (agriculture or mining), using the sizes of inhabited areas, occurrence of certain monuments, and documentation of civic statuses as proxies for these activities. We have also restricted our investigation to entertainment structures that were either built or rebuilt in the Imperial period (i.e., between the first century BCE and third century CE). This is the time when most theaters and amphitheaters were in use and is the period for which we have the most abundant evidence. Finally, we only focus on the theaters and amphitheaters associated with cities and towns, not those associated with sanctuaries or military sites.

### Inhabited Areas, Densities, and Numbers of Residents

Although various approaches have been suggested for estimating the populations of Graeco-Roman settlements, the most common method involves measuring the extent of the inhabited area and then multiplying this by a range of population densities.\textsuperscript{23} We follow the same approach here, again drawing on Hanson’s catalogue, which includes estimates for the sizes of the inhabited areas of 885 sites based on several features, including the area enclosed by walls, the extents of urban grids, the sizes of residential zones, the situation of cemeteries, and the character of natural features such as changes in relief, rivers, and coastlines.\textsuperscript{24} We converted inhabited areas to population estimates using the relationship between the sizes and densities of sites derived in earlier work, based on the evidence for the number of residential units in the cleared portions of a sample of 50 sites from throughout the Graeco-Roman world, assuming an average of five persons per household (including men, women, children, and a small number of slaves).\textsuperscript{25} The latter figure is based on cross-cultural comparisons, supported by census material from Hellenistic and Roman Egypt. This evidence demonstrates that there is indeed a strong relationship between the inhabited areas and population densities of Graeco-Roman cities that is consistent with both theoretical and empirical work.

\textsuperscript{25}Hanson and Ortman 2017.
in a range of settings. Although this relationship can only be used as a guideline, it does allow us to estimate site populations independently of the capacities of theaters and amphitheaters, allowing us to examine the relationship between them in a consistent fashion for the first time.

ENTERTAINMENT STRUCTURES

The theaters and amphitheaters we consider in this article were venues for a wide range of activities, including dramas (ludi scaenici), recitals, lectures, gladiatorial fights and wild beast hunts (munera and venationes), circus acts, and executions, all of which were hugely popular (albeit to different degrees with different sections of the community). These were venues for collective events that played central roles in fostering social cohesion through the shared performance and observation of social, cultural, religious, and political activities, as well as through the expression of civic identity and loyalty to the imperial regime, identification of insiders and outsiders, and illustration of the consequences of falling out of line. In addition, most of the events staged in these structures were distinctive, largely unrepeatable events that carried significant meaning for those who witnessed them and were likely to be discussed beyond their immediate context. This is borne out by graffiti from Pompeii and various other sites, which not only record the names of individual combatants but also the outcomes of specific contests (such as whether a gladiator was let off with his life or not), as well as by the existence of both glasses and lamps decorated with scenes of combat and the manufacture of statuettes that are often interpreted as souvenirs. For all these reasons, entertainment structures are appropriate for the theoretical approach developed above.

It is important to think carefully about the design and function of these structures. Although theaters and amphitheaters can be regarded as venues in which individuals interacted, these interactions did not take the same form of social mixing as we have discussed elsewhere, where we concentrated on day-to-day encounters in the street or public spaces, rather than at collective events. Instead, the architecture of theaters and amphitheaters reflects a concern for social control, since audiences were rigorously segregated on the basis of class, gender, nationality, profession, and marital status. This is reflected in the design of these structures, which restricted access and facilitated the routing of spectators to the appropriate section of seating. In both theaters and amphitheaters, the cavea was often divided into five horizontal sections, known as maeniana, corresponding to hierarchical divisions of the community: the imperator and senatores, equites, plebs, women and children, and slaves. The seating arrangements of these structures thus reflected tightly defined groupings that encoded strong social divisions within the community. We do not regard this as problematic for the current argument because all who attended events in an entertainment structure received more or less the same social information and could subsequently share it with their social contacts (although what they focused on and how it was recounted would vary from person to person). Meanwhile, although there is some evidence that certain entertainment structures were initially built for the benefit of specific groups (say, citizens or colonists), there is less evidence

26 Bettencourt 2013; Ortman et al. 2014.
27 Special note needs to be taken of Pompeii. As Osanna has shown in an important article, we might be able to come up with new evidence for the population of the site based on a newly discovered inscription from just outside the Porta Stabia, which records the donation of a banquet for 6,840 individuals on 456 dining couches (each seating 15 individuals) to the people of Pompeii (Osanna 2018, 315–16). This leads him to suggest a total population of some 30,000, assuming the banquet was restricted to adult males. It seems more likely, however, that the recipients would have included both the residents of the city and its hinterland, in keeping with the ancient practice of treating the two as one unit, especially since this figure would suggest a population density of around 500 people per hectare for the whole site, which would be extremely large by comparative standards. We therefore follow earlier work in using the size of the inhabited area and the densification effect discussed above to estimate the population of the site and obtain a figure almost identical to earlier estimates based on the available stock of housing (Flohr 2017, 53–68; Hanson and Ortman 2017, 321).

for whether or not these distinctions were rigorously or continuously upheld.

In what follows, we focus on theaters and amphitheaters, the most common types of entertainment structures. There is some overlap in the design and function of these structures, so one should not assume that specific activities were necessarily restricted to one or the other. As there are only a few sites that contained both kinds of structures, we have treated them separately in the sections below.

To identify sites with entertainment structures, we draw once again on Hanson’s catalogue, which incorporates information from a range of sources. These include Sear’s *Roman Theaters*, which uses a mixture of literary, archaeological, and epigraphic evidence to provide a catalogue of all known theaters in the Roman world in the Imperial period. This source contains about 1,000 entries, including theaters and other buildings of a theatrical type such as odea, theater-amphitheaters, and theater-sanctuaries, many of which are illustrated by architectural drawings. In addition, it includes information on overall dimensions, orchestra and cavea widths, orchestra and cavea areas, and, occasionally, seating capacities. Additional sources include Golvin’s *L’ amphithéâtre romain*, which provides a catalogue of about 200 amphitheaters in the Roman world in the Imperial period. This source includes or excluding them does not make a material difference in the results. Similarly, we do not have much information on the capacities of circuses and hippodromes, simply because they are relatively rare by the standards of theaters and amphitheaters and relatively little work has been done on them. For these reasons we limit the investigation here to theaters and amphitheaters.

Although earlier structures exist at some sites, we have only looked at theaters that were built or rebuilt during the Imperial period unless there is evidence that they were modified during the same time frame, such as through an extension or reduction in the size of the cavea and any concomitant changes in orchestra or stage buildings (there are examples of both kinds of changes). The same concern does not apply to amphitheaters, since they all date to the Imperial period. There are a few cases in which we could record changes in the capacity of a theater or amphitheater over time. For the purposes of this article, we simply use the largest figure documented for the Imperial period, so as to compare the peak capacities of entertainment structures with the peak populations of the settlements in which they occur. It should also be noted that a few theaters were converted in the Imperial period by turning the orchestra into an arena, so they effectively had a dual use as both theaters and amphitheaters.

We have marked these in the supporting materials but note that including or excluding them does not make a material difference in the results.

The most common method for estimating the capacities of entertainment structures involves simple formulas that approximate the shapes of both kinds of structures based on evidence for their basic dimensions, such as the overall lengths, breadths, and widths of their seating areas and event spaces. As Rose has shown, we can calculate the surface area of the cavea in a theater by treating it as a half annulus, which can be derived by subtracting the area of one semicircle from the area of another semicircle. This can be achieved with a simple formula: \((\pi \times r_1^2) - (\pi \times r_2^2)\), where \(r_1\) is the radius of the exterior semicircle (i.e., the whole structure) and \(r_2\) is the radius of the interior semicircle.

41 Rose 2005, 115–16.
semicircle (i.e., the orchestra).\textsuperscript{42} This equation is not ideal, since the cavea often extended more than 180° around the orchestra (this is especially common in the Greek world). We have therefore visually identified such cases from the diagrams in Sear's catalogue and conducted the same analyses both with and without them. As we see below, although this does account for some of the most severe outliers from the overall relationships, it does not make much difference to the average relationship (although we do acknowledge that measuring structures directly from maps and plans would be one way to improve our analysis in the future). In the meantime, we can calculate the surface area of the cavea in an amphitheater by treating it as a hollow oval and then using a similar method. This can be done using the formula: \((a + 2) \times (b + 2) \times \pi - (a + 2) \times (b + 2) \times \pi\), where \(a\) and \(b\) are the lengths and widths of the exterior oval (i.e., the whole structure) and \(a\) and \(b\) are the lengths and widths of the interior oval (i.e., the arena).\textsuperscript{43} This equation is also somewhat of a compromise, given that many amphitheaters were not perfect ovals.\textsuperscript{44} The effects of this are a little more difficult to assess, since there are no hard and fast rules for calculating the amount that each structure deviates from an oval based on maps and plans, but they are generally not as pronounced as with theaters. Since Sear did not include estimates for the sizes of each cavea, we have used the equation above to estimate their seating areas. In contrast, given that this information for amphitheaters is already provided in both Golvin's and Bomgardner's catalogues, we have simply used their figures (which are based on the same strategy).\textsuperscript{45} As Rose has pointed out, these areas would have also included some space for access and services, such as entrances and exits, staircases, and circulation aisles.\textsuperscript{46} Although the exact area that was taken up by these would have varied from building to building, we have followed Rose and most other scholars in assuming that they would have occupied, on average, about 10% of the surface area in question, and we have reduced the estimates of seating capacities accordingly.\textsuperscript{47}

With these seating areas in hand, we then estimate the numbers of spectators by assuming that there was a certain amount of space per person. To do this, we follow Rose, who has offered a variety of estimates of the area per seat, which range from a minimum of 0.3 m wide x 0.5 m deep per spectator (i.e., 0.15 m\(^2\) each) to a median of 0.4 m wide x 0.7 m deep per spectator (i.e., 0.28 m\(^2\) each) and a maximum of 0.5 m wide x 0.8 m deep per spectator (i.e., 0.4 m\(^2\) each).\textsuperscript{48} These are based on a combination of textual and archaeological evidence (such as Vitruvius's \textit{Ten Books on Architecture} and markings on the seats of some structures) and contemporary guidelines for modern facilities.\textsuperscript{49} In particular, although Vitruvius recommends an average depth of 0.6 to 0.7 m, he does not comment on the width, which is derived from remains at Arles and Pola.\textsuperscript{50} We have used the median seating area of 0.28 m\(^2\) to convert the estimates for seating areas of each structure into estimates of the numbers of spectators in each one. This figure can be applied to the entire group of theaters and amphitheaters discussed below, especially given that there is no evidence that seating areas in entertainment structures in larger sites were any more or less cramped than those in smaller ones. We should not set too much store in the absolute value of figures, given that even a small change in these parameters (such as 10 cm) would have a significant effect on the surface area that has been allowed per spectator and therefore on the estimates for the total capacities of these structures.\textsuperscript{51} This should not have any effect on the overall relationship across sites, however, since we have used the same conversion for the seating area per person for all sites (it is thus a constant in our calculations).

Our analysis assumes that both theaters and amphitheaters were usually filled to capacity and that most of the audience was seated rather than standing. There is no way to test these assumptions using the available evidence (although the amount of seating pressure might be detectable in the residuals to the overall relationship, as we see below). It is important to point out, however, that, although we would expect both theaters and amphitheaters to have made important statements for their builders, we would not expect builders to have

\end{itemize}
incurred any unnecessary expenditure in the construction of seating areas, if only because such funds could have been better spent on underwriting more impressive events or more lavish amenities for spectators. We also do not know how often events were staged, although we can assume that they occurred more often in larger sites.

It should also be remembered that the total number of people who interacted with these structures could have been a little higher than their seating capacities, since we know that individuals gathered outside as well as inside entertainment structures. For example, Tacitus refers to people who were attending the spectacle as well as people who were standing around the actual building as being caught up in the collapse of the amphitheater at Fidenae in 27 CE.\textsuperscript{52} Many of these structures had dedicated retail spaces on their outsides as well. Nevertheless, we would expect the numbers of nonseated individuals to have been small relative to the number of people inside.

In the case of the imperial capital, we have used Rose's figures for the seating areas of the Theater of Marcellus and the Colosseum, which are 5,471 m\textsuperscript{2} and 18,006 m\textsuperscript{2}, respectively (minus access and service areas). These figures suggest these structures could have held 19,539 and 64,308 spectators, respectively.\textsuperscript{53} We then added our own estimate for the Theater of Pompey and the Theater of Balbus, based on more recent work that suggests, respectively, seating areas of about 6,749 m\textsuperscript{2} and 3,007 m\textsuperscript{2} and capacities of 24,103 and 10,739 spectators.\textsuperscript{54} Although we are aware of the existence of several other amphitheaters at Rome, such as the Amphitheater of Statilius Taurus, Amphitheater of Caligula, and Amphitheater of Nero, it is usually assumed that these had either been demolished or had burnt down by the time of the construction of the Colosseum (the Ludus Magnus is usually regarded as a training school and the Amphitheatrum Castrense is a little later and was attached to an imperial residence), so we do not include these structures here. Although there are a couple of other sites with more than one entertainment structure, most only have one, meaning that we either have complete information for most sites or none at all.

INVESTIGATING SCALE-ADJUSTED VARIATION

As we show below, one of the advantages of the approach used in this article is that it allows one to control for the effects of scale, thus revealing the extent to which entertainment structures at specific sites are larger or smaller than we would expect based on the population of their associated settlement. This scale-adjusted deviation from the average relationship is referred to as a residual. Although archaeologists have typically regarded residuals as a reflection of error, it is also possible to regard them as a reflection of meaningful differences in the social and economic conditions at each site, which are therefore referred to as scale-adjusted urban indicators.\textsuperscript{55} We would expect such deviations to result from a range of factors that are not included in the theoretical model discussed above. In the context of entertainment structures, we might expect residuals to correlate with the overall wealth, status, and influence of sites. For example, we might expect the sites with the greatest wealth and status to have had theaters and amphitheaters that are larger than would be expected based on their population (i.e., the capacities of their entertainment structures exceeded the needs of their inhabitants).

To test this possibility, we examined correlations between residuals and other attributes of sites, of which the most important is a site’s civic status. These data are derived from Hanson’s catalogue, which includes most of the available information offered by standard sources.\textsuperscript{56} Civic statuses are notoriously complicated, since they were never properly rationalized, were subject to constant negotiation, and were open to extensive abuse, but we can group them into four broad categories: the capital of the empire, provincial capitals, coloniae, and municipia. These categories are obviously a simplification of the range of civic statuses enjoyed by specific sites, but they are sufficient for our purpose, which is to offer a coarse-grained classification of the overall standing of each site that incorporates a variety of factors, such as its historical importance or its role in the administration of the empire. Since the status of cities changed over time, we have used the highest status attained by each city, on the assumption that this status should bear the closest resemblance to its estimated population, which is usually based on its maximum extent.

\textsuperscript{56}Hanson 2016a, 83.
Next, we captured basic information about both the numbers of people living in neighboring cities and the carrying capacity of the hinterlands of each site. Although it is not possible to reconstruct these hinterlands in detail, we can estimate their extents using simple ring buffers representing one day’s travel from the center of each site, on the grounds that we would not expect most spectators to have traveled for more than one day to reach an event.\(^57\) This distance can be based on modern handbooks, which suggest that an individual of average health and fitness can cover approximately 5 km in about an hour on foot, or about 40 km in eight hours.\(^58\) This figure is also supported by estimating the distance between Pompeii and the other sites in the advertisements for events referred to above, since most of them are within 40 km and the average distance from Pompeii is about 35 km (see fig. 1, table 1). Although one could use cost surfaces to take account of differences in the landscape, such as elevation, rivers, and seas, that might make it easier or harder to traverse, such details should not make much difference to the results, given the scale of our analysis.

The numbers of people living in neighboring cities has been calculated by simply summing the known estimated populations of the cities in each ring buffer. Although it is not possible to estimate the numbers of people living in rural areas based on current evidence, it is possible to use the natural endowment of the landscape as a rough index of the numbers of individuals who might have lived on the land. Here, we have used Galor and Özak’s caloric suitability indices, which give us an indication of how the total numbers of calories that could have been derived from each of the crops that were available for cultivation in the pre-1500 CE era varied from region to region (and therefore a rough indication of the relative numbers of individuals who could have been fed in a given area—i.e., the carrying capacity of the area).\(^59\) We combined this model with the ring buffers to calculate the average numbers of calories available to each site, giving us a crude sense of how much the average carrying capacity varied from site to site.

\(^{58}\) Wheatley and Gillings 2002; Conolly and Lake 2006; Hanson 2016a, 88.

Finally, by considering the distances between sites and both seas and rivers as recorded in Hanson’s catalogue (we have not included roads, since we would expect all the sites to be located at or near important intersections), we obtained a rough indication of how well connected sites were, again taking this information from Hanson’s catalogue.\(^60\)

RESULTS

Of the 783 theaters and 330 amphitheaters known for the Graeco-Roman world, we have evidence for the capacities of 173 theaters and 107 amphitheaters (figs. 2, 3; for the full list, see tables in the online appendix).\(^61\) These data derive from 238 sites distributed throughout the Roman world and dating from the Imperial period, with estimated populations ranging from under 1,000 to almost a million inhabitants. Of these sites, 43 have both a theater and an amphitheater.

We assess the relationship between the populations of cities and the capacities of their theaters and amphitheaters through standard regression techniques applied to the log-transformed data (figs. 4, 5, table 3).\(^62\) We have also calculated the residual of the capacity for each city given the value predicted by each regression.

These results show that there is indeed a systematic relationship between the estimated populations of cities and the capacities of both theaters and amphitheaters. The slopes of the best-fit lines for these relationships (the lines that best describe the data, represented by the dotted lines in figs. 4 and 5) are almost identical to each other, exhibiting similar values of about one-third (in other words, the capacities of both theaters and amphitheaters increase at the same rate, but much slower than the population). In light of the theoretical discussion above, this result suggests that, in the average city, the social information conveyed through events in entertainment structures could have spread to the entire urban population through an average of two intermediaries (\(h = 2\)).

\(^{60}\) Hanson 2016a.

\(^{61}\) Hanson 2016a, 79. See AJA Online for this article’s online-only appendix.

\(^{62}\) These relationships were assessed using a common form of regression that employs ordinary least-squares regression and log-transformed data. This is feasible because \(C = c_0 N^\beta\) and log \(C = \beta \log N + \log c_0\) are equivalent expressions, meaning that one can estimate the exponent and pre-factor of the power function by estimating the slope and intercept of the linear function fit to the log-transformed values.
Fig. 2. Locations of the theaters investigated in this study. The sizes of the location dots are proportional to the seating capacities (in number of persons) of the structures.

Fig. 3. Locations of the amphitheaters investigated in this study. The sizes of the location dots are proportional to the seating capacities (in number of persons) of the structures.
FIG. 4. The relationship between the estimated populations of sites and the estimated seating capacities of theaters (in persons). The dotted line represents the best-fit line, which indicates the average relationship between the population sizes and the seating capacities of theaters. The equation of the best-fit line is shown in the inset, where y is the capacity of the theater in question, x is the population of the site, and the numerals are the y-intercept and the exponent of the relationship. The $R^2$ is a measure of how much variation in the capacities of theaters is accounted for by variation in the populations of sites. Both scales are logarithmic. This exercise reveals that although there is a consistent relationship between these variables, it is not linear; instead, the capacities of theaters increase much more slowly than the populations of sites.

FIG. 5. The relationship between the estimated populations of sites and the estimated seating capacities of amphitheaters (in persons). The dotted line represents the best-fit line, which indicates the average relationship between the population sizes and the seating capacities of amphitheaters. The equation of the best-fit line is shown in the inset, where y is the capacity of the amphitheater in question, x is the population of the site, and the numerals are the y-intercept and the exponent of the relationship. The $R^2$ is a measure of how much variation in the capacities of amphitheaters is accounted for by variation in the populations of sites. Both scales are logarithmic. As with theaters, although there is a consistent relationship between these variables, it is not linear; instead, the capacities of amphitheaters increase much more slowly than the populations of sites.
result is remarkable, given the wide range of factors one might have expected to affect the results. It is also worth noting that removing entertainment structures with irregular forms or that were modified in the Imperial period makes no meaningful difference in the results (e.g., removing theaters with nonsemicircular caveae yields an exponent of 0.338, while removing the theaters that had been modified gives 0.358, almost no change). The results suggest that the structures in question might have had similar roles and that the overall relationship between city population and entertainment structure capacity was very robust.

**Discussion**

Although our analysis shows that the capacities of entertainment structures did increase as the populations of cities increased, this relationship was far from linear: the populations of sites tended to grow much faster than the capacities of their entertainment structures. This relationship implies that a smaller fraction of urban residents could have attended an event in an entertainment structure in larger cities (and this fraction decreases at a consistent rate across the full range of city sizes). It is also interesting to observe that there is a correlation between the capacities of theaters and amphitheaters in the west and cities in the west deviate from the theater-size and amphitheater-size relationships. Although the decision about whether to build a theater or amphitheater might have been culturally informed, any decisions about how large or small it should be are more likely to be a product of the specific needs of the community it was destined to serve.

Although it is important not to put too much faith in specific figures for specific sites, an interesting aspect of our results is that they suggest that the capacities of theaters and amphitheaters in the smallest sites were often several times larger than their resident populations. Smaller sites might thus have been more likely to have provided for both themselves and their neighboring surroundings, while it would have been difficult for the largest sites to have provided for more than a fraction of their own

---

### Table 3

The results of regressing the capacities of both theaters and amphitheaters against the estimated populations of sites. The independent variable is the estimated population in all cases, while the dependent variable is the capacities of either theaters or amphitheaters. This procedure allows us to estimate the slope of the relationship (the exponent) and a baseline amount for each kind of structure (the pre-factor), along with confidence intervals (CI), a measure of how much variation in one variable is accounted for by variation in the other (the R²), and an index of their statistical significance (the p-value). Despite the modest R² values, all regressions are significant at the p<0.0001 level. Note that exponents of the relationships between the capacities of entertainment structures and estimated populations for sites are almost identical for both theaters and amphitheaters.

Capacities of Entertainment Structures in the Roman Empire

...it is possible, therefore, that the function of entertainment structures changed somewhat as the size of the sites they are associated with increased. This observation gives us a new view of both theaters and amphitheaters that might help resolve the uncertainties about their design and function referred to in our introduction. If true, it also raises the interesting possibility that at least some of this deficit might have been made up by putting on events more frequently in larger sites, in keeping with our sense that larger sites were more affluent. Regardless, the consistent slope of the relationships between population and entertainment structure capacity shows that the fraction of the overall social network of a city that could attend events in an entertainment structure decreased in a consistent way across cities of all sizes. Given this, an important question for future research is whether the size of the overall social network (i.e., the number of people who regularly interacted with one another in a city, regardless of whether they dwelt within it) increased faster than, slower than, or at the same rate as city population. If the size of the social network increased faster than the population of the central city, it would mean that the fraction of this social network that could attend events in entertainment structures would decrease even faster than we observe for the city itself (i.e., the slope of the best-fit lines would be less than 1/3; see figs. 4, 5); and, if the size of the social network increased more slowly than the population of the central city, it would imply that this fraction decreased less rapidly than observed (i.e., the slope would be more than 1/3).

The results are consistent with a model of information percolation in social networks in which the initial number of witnesses was a fraction of the city population given by $N^{\beta}$, with $\beta = 1/3$, and with an average path length, $h$, of 2. In such a social network, everyone would have received the news in no worse than a secondhand account, and we can conclude that the social networks of these cities were sufficiently functional for information to have been disseminated throughout the community and that these communities were sufficiently connected to have maintained a sense of shared local identity. We also note that these results are consistent with contemporary real-world networks, including social networks, which are characterized by high clustering and small average path lengths (networks often called small worlds, after the likelihood that each person is linked to every other person through a small number of mutual network paths).
Fig. 7. The relationship between the estimated populations of sites and the percentages of the population served by theaters (percentages generated by dividing the same capacities as shown in fig. 4 by the estimated population of each site, multiplied by 100). The equation of the best-fit line is shown in the inset. Both scales are logarithmic. Note that the capacities of theaters associated with smaller sites are often several times larger than the population, while those in larger sites are often a fraction of it.

Fig. 8. The relationship between the estimated populations of sites and the percentages of the population served by amphitheaters (percentages generated by dividing the same capacities as shown in fig. 5 by the estimated population of each site, multiplied by 100). The equation of the best-fit line is shown in the inset. Both scales are logarithmic. Note that the capacities of amphitheaters associated with smaller sites are often several times larger than the population, while those in larger sites are often a fraction of it. Theaters show the same relationship (see fig. 7).
Individual sites rarely fall exactly on the best-fit line (see figs. 4, 5). Instead, the observed capacities for most sites are greater than or less than the expected value for their sizes and populations. This variation is represented by the residuals (that is, the vertical deviation from the best-fit line) for each site and structure type. These residuals reflect a range of factors, including not only error in the area and density estimates for sites (and therefore their population estimates) but also error in the estimated capacities of structures, as well as slight mismatches in time between entertainment structure construction and peak urban population and any misjudgments by patrons and architects regarding current and future demand for entertainment space. Having said this, we would expect all of these errors to be independent of the sizes of sites (i.e., for them to be unstructured relative to site size), and, if so, there may be patterns in the residuals that reflect meaningful differences in local social and economic conditions. This seems to be borne out by the fact that, across sites containing both theaters and amphitheaters, the magnitude of the theater residual is correlated with the magnitude of the amphitheater residual (fig. 9). This observation is consistent with the idea that a common set of factors determined the deviation of both kinds of entertainment structures from the average relationship. It is also encouraging that positive and negative residuals seem to cluster together in some areas; for example, there are clusters of positive residuals (larger-than-expected theaters or amphitheaters) in parts of Gaul and clusters of negative residuals (smaller-than-expected theaters or amphitheaters) in North Africa (figs. 10, 11).

Figures 12 and 13 and tables 4 and 5 summarize the magnitudes of the residuals for, respectively, the relationships between population and theater capacity and between population and amphitheater capacity in accordance with the highest civic status associated with each city. Although the results are not statistically significant, they are nonetheless strongly patterned, with more positive residuals generally being associated with higher-status sites. Specifically, provincial capitals have the largest positive average residuals for both theaters and amphitheaters, followed by increasingly negative average residuals for coloniae and municipia. This result is very much in line with our sense of the overall importance of these different classes of settlements in the administrative structure of the empire. In short, these patterns suggest that more important sites were more likely to have had larger theaters or amphitheaters than we would expect for a city of their size.

It is striking, however, that there is no relationship between the sizes of residuals and the other attributes described above, which suggests that there is no single explanation for the overall trend between the residuals and the statuses of sites (table 6). There are clearly some sites that had a rich tradition of monumental construction and might have attracted more elite expenditure, other sites that were located in dense networks that might have attracted more visitors from elsewhere, and still other sites whose deviation is more difficult to understand (a possible indication that our information about them is less than complete). There also does not appear to be any special link between sites with forts and scaling residuals. Although we do not believe the magnitudes of individual residuals are meaningful, because of the various sources of error in our data these analyses do suggest that there are patterns in the residuals across groups of sites that potentially reflect additional dimensions of the social and economic contexts of cities and their effects on the development of entertainment structures.

Another interesting outcome of the residual analyses is that Rome is a positive outlier from the relationship between population and theater capacity but a negative outlier from the relationship between population and amphitheater capacity (as illustrated by the...
magnitude of the residuals, which are about 0.17 and −0.05, respectively). Even though Rome had by far the largest entertainment structures in the empire, it may still have been somewhat underserved in terms of its amphitheater capacity.64 This raises the question of whether the size of this negative residual reflects some other restricting factor, such as visual and auditory limits. As Rose has shown, we can examine the effectiveness of entertainment structures by considering the abilities of spectators to see and hear events, based on a spectator’s maximum viewing angle of 120°, a distance of 60 to 90 m, and a maximum listening distance of 42 m to the front, 30 m to the sides, and 17 m to the rear.65 These limits were approached by entertainment structures in the capital. This suggests that limits of human perception, rather than the limits of building materials or construction techniques, might have been a primary constraint on the capacities of these structures and therefore on the extent to which social information could be disseminated through entertainment structures in the absence of technological aids.66 This observation might in turn have implications for the maximum size of settlements that could be sustained as functional socioeconomic and spatial organizations in preindustrial settings before the advent of other ways of disseminating information, such as newspapers and broadcast media. In this context, it may be significant that Rome, the capital, would not be surpassed in size by another city until London did so sometime between 1800 and 1850, around the same time that fundamental changes were starting to be made in forms of and access to entertainment (such as the advent of modern theaters and the spread of music halls), along with nascent forms of mass media.67

66 See Moore 1996 and Bowser and Patton 2004 for additional applications of this idea.
FIG. 10. The deviations (residuals) of sites from the expected relationship between the capacity of the theater at a site and the size of its population. Green arrows indicate positive residuals (larger-than-expected theaters); red arrows indicate negative residuals (smaller-than-expected theaters).

FIG. 11. The deviations (residuals) of sites from the expected relationship between the capacity of the amphitheater at a site and the size of its population. Green arrows indicate positive residuals (larger-than-expected amphitheaters); red arrows indicate negative residuals (smaller-than-expected amphitheaters).
fig. 12. The deviations (residuals) of sites from the relationship between theater capacity and population size. Each bar represents a site and is color coded by the civic status of the site. Note that the residuals of provincial capitals are more often positive, while the residuals of municipia are more often negative.

fig. 13. The deviations (residuals) of sites from the relationship between amphitheater capacity and population size. Each bar represents a site and is color coded by the civic status of the site. Note that the residuals of provincial capitals are more often positive, while the residuals of municipia are more often negative. A similar phenomenon is seen with regard to theaters (see fig. 12).
Finally, we note that Pompeii is also a significant outlier from the relationship between population and amphitheater capacity, with a large positive residual of 0.28, an indication that it had a relatively large amphitheater for a city of its size. Pompeii's large amphitheater may reflect the evidence, discussed above, that the city attracted a large number of visitors from elsewhere, including Nuceria. Perhaps we should ask whether the kind of intercity rivalry described by Tacitus in the context of the Pompeian-Nucerian riot was normal for the Roman world (as assumed by most scholars) or whether we might better regard it as a relatively unusual consequence of the large numbers of visitors that could attend events at Pompeii.
Our results also highlight the flexibility of the overall relationships discussed above by demonstrating how much sites may vary while still conforming to the same underlying relationships. The variation might help explain why there has been so much difficulty using the capacities of entertainment structures to estimate the populations of sites, since it suggests that, although there is a general relationship between them, there is enough variation that using entertainment structures to estimate the populations of sites is not reliable. At the same time, these results underscore the potential of using the deviations from the overall relationships as a reflection of the different dimensions of the sites.

CONCLUSIONS

In this article, we have argued that one can think of human settlements as built environments that, in addition to facilitating the flow of goods and services, also facilitate the percolation of social information. This view leads to a model concerning the expected capacities of structures devoted to public entertainment. The model suggests that, as the population of a site increases, the fraction of the population that attends such events can decline, with no loss of functionality, because of the increasing connectivity of individuals in larger and denser settlements. We have tested this model using estimates of the sizes of the populations and the capacities of entertainment structures at several hundred Graeco-Roman cities and shown that there is indeed a systematic overall relationship between these urban indicators. Specifically, we find that the capacities of entertainment structures were sufficient, on average, for the social information conveyed at a public entertainment to reach the whole urban population through firsthand accounts of attendees and secondhand accounts of those informed by attendees. This result suggests that in Graeco-Roman cities there were sufficiently connected social networks to sustain the percolation of social information from eyewitnesses to the rest of the community.

We have also argued that we can use the extent to which each site deviates from these overall relationships as a reflection of its unique social and economic conditions (which we call scale-adjusted urban indicators), and we have examined a variety of factors that might be expected to have influenced the deviation of these structures from their expected values. Our results, although preliminary, indicate that there is a suggestive pattern in the scale-adjusted entertainment structure capacities and the overall standing of sites as reflected in their civic statuses. We believe that when the data are of sufficient quality, the residuals of scaling relationships can be used to reveal variation in social and economic conditions after taking the effects of population size into account.

Future work could expand on these results in several ways. First, investigators could seek to stratify the data into time periods and regional groups to investigate how deviations from the underlying scaling relationships varied over time or across space. Second, investigators could further improve our ability to estimate the populations of Graeco-Roman cities by incorporating multiple scaling relationships (area, residential density, entertainment structure capacity, forum or agora area) into the estimation process. Third, investigators could examine additional factors we have not considered to account for patterns in the residuals of the relationship between population and structure capacity.
